

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

*On the Symptoms and Treatment of
Natural Labours.*

WHEN the foetus has completed the period of its existence in the uterus, it can live no longer in the same condition, and the great nervous and muscular structures of the organ, which have lain dormant during pregnancy, are suddenly roused into action in consequence of the stimulus imparted to them by the mature foetus, and the whole contents of the uterus are expelled. This process, which is always attended with pain and danger, is called *labour*, *delivery*, or *parturition*; all the varieties and complications of which have been arranged by Smellie and Denman in a regular systematic manner, under the four following heads:—

1. *Natural labour*, in which the head of the foetus presents or comes first; and the delivery is accomplished in twenty-four hours, by the natural contractions of the uterus and the assistance commonly given.

2. *Lingering, tedious, protracted, and difficult labour*, in which the head of the foetus likewise presents, but the labour continues upwards of twenty-four hours, and some unusual assistance is required. Irregular uterine action, nervous exhaustion, rigidity of the parts, cicatrices of the vagina, tumors of various kinds within the pelvis, and distortion of the pelvis, and unfavourable position, or unusual size of the foetal head, are the most common causes of

the difficulty experienced in the cases referred to this class, and which terminate either without manual or instrumental assistance after unusual suffering, or by the employment of the forceps or perforator.

3. *Preternatural labour*, where the nates, the inferior or superior extremities, present; or the umbilical cord is prolapsed; or there is a plurality of children.

4. *Complicated labour*, in which some dangerous accident occurs, unconnected with the presentation of the foetus: as uterine hæmorrhage, retention of the placenta, inversion or rupture of the uterus, puerperal convulsions.

This classification of labours is both natural and artificial; and for all practical purposes it is the best which has yet been proposed.

1. *Of the Symptoms and Treatment of
Natural Labour.*

In natural labour the head of the foetus presents, and the delivery is generally completed in twenty-four hours, and no artificial assistance is required. In every case the os uteri, vagina, and external parts, are dilated, the membranes ruptured, the child expelled, and the placenta and membranes separated and forced from the uterus. The dilatation of the os uteri, rupture of the membranes, and escape of the liquor amnii, take place in the first stage of labour. When the os uteri is fully dilated, and the head has passed through the os uteri, the first stage of labour is completed. The entire expulsion of the head, trunk, and extremities of the child, is effected in the second stage of labour; and in the third stage the placenta and membranes are detached from the inner surface of the uterus, and completely expelled both from the uterus and vagina. In the greater number of cases, before the first stage of labour has been fully completed the second has commenced and made some progress; and it is not unusual for the head

WHEN the foetus has completed the period of its existence in the uterus, it can live no longer in the same condition, and the great nervous and muscular structures of the organ, which have lain dormant during pregnancy, are suddenly roused into action in consequence of the stimulus imparted to them by the mature foetus, and the whole contents of the uterus are expelled. This process, which is always attended with pain and danger, is called *labour*, *delivery*, or *parturition*; all the varieties and complications of which have been arranged by Smellie and Denman in a regular systematic manner, under the four following heads:—

1. *Natural labour*, in which the head of the foetus presents or comes first; and the delivery is accomplished in twenty-four hours, by the natural contractions of the uterus and the assistance commonly given.

2. *Lingering, tedious, protracted, and difficult labour*, in which the head of the foetus likewise presents, but the labour continues upwards of twenty-four hours, and some unusual assistance is required. Irregular uterine action, nervous exhaustion, rigidity of the parts, cicatrices of the vagina, tumors of various kinds within the pelvis, and distortion of the pelvis, and unfavourable position, or unusual size of the foetal head, are the most common causes of

the difficulty experienced in the cases referred to this class, and which terminate either without manual or instrumental assistance after unusual suffering, or by the employment of the forceps or perforator.

3. *Preternatural labour*, where the nates, the inferior or superior extremities, present; or the umbilical cord is prolapsed; or there is a plurality of children.

4. *Complicated labour*, in which some dangerous accident occurs, unconnected with the presentation of the foetus: as uterine hæmorrhage, retention of the placenta, inversion or rupture of the uterus, puerperal convulsions.

This classification of labours is both natural and artificial; and for all practical purposes it is the best which has yet been proposed.

1. *Of the Symptoms and Treatment of
Natural Labour.*

In natural labour the head of the foetus presents, and the delivery is generally completed in twenty-four hours, and no artificial assistance is required. In every case the os uteri, vagina, and external parts, are dilated, the membranes ruptured, the child expelled, and the placenta and membranes separated and forced from the uterus. The dilatation of the os uteri, rupture of the membranes, and escape of the liquor amnii, take place in the first stage of labour. When the os uteri is fully dilated, and the head has passed through the os uteri, the first stage of labour is completed. The entire expulsion of the head, trunk, and extremities of the child, is effected in the second stage of labour; and in the third stage the placenta and membranes are detached from the inner surface of the uterus, and completely expelled both from the uterus and vagina. In the greater number of cases, before the first stage of labour has been fully completed the second has commenced and made some progress; and it is not unusual for the head

to descend through the brim and cavity to the outlet of the pelvis, and begin to press upon the external parts, before the complete dilatation of the os uteri has been effected.

FIG. 1 represents the progress of the first stage of labour.

For several days before labour supervenes there are often certain symptoms observed which have been called the precursory or premonitory symptoms of labour. The first and most striking of these is a subsidence or sinking down of the uterus. The epigastric region, in consequence of this, becomes less distended, respiration is performed with greater ease, and the patient feels herself more comfortable, and more disposed and able to exert herself than she had been for some time before. This sinking down of the uterus is not from a mechanical cause, but from relaxation of the parts, and is often observed in the lower animals before parturition.

A sensation of weight in the inferior part of the pelvis and in the region of the uterus, and irritation of the bladder and rectum, often accompany this subsidence of the

Not only do the parts become soft

pains of labour are experienced, there is a mucous discharge from the vagina tinged with blood, arising from the dilatation of the orifice of the uterus, and the separation of the membranes. Some women suffer for a week or more before labour begins from sleeplessness at night, irregular pains about the uterus, and a peculiar nervous irritability. Some have at the first a sharp pain or uterine contraction, in a few hours another, and a few more after long intervals; whilst in others without pains the membranes are ruptured, and the liquor amnii escapes. These pains are sometimes experienced fifteen or twenty hours before the commencement of regular uterine action. They are then slight, produce little effect upon the constitution, and come at intervals of a quarter or half an hour, the intervals gradually becoming shorter, and the uterine contractions stronger. During these periodical pains the os uteri is opened, and its margin

becomes tense and stretched, and a slight degree of pressure is felt on the extremity of the finger, if an examination be made. As soon as the pain or uterine contraction subsides, this state of tension or stretching of the lips of the orifice of the uterus ceases, and the orifice itself again closes. The membranes are put upon the stretch also during the pains; but at first they do not protrude through the orifice. Gradually these pains, which are often called cutting or grinding, become more and more severe, continue longer, recur at shorter intervals, and leave a certain degree of uneasiness when they are absent; and each pain is sometimes preceded by a slight tremor or shivering; and sickness, vomiting, restlessness, impatience, and despondency, are often present during the whole of the first stage of labour. The action of the heart and arteries becomes increased, the skin hot, and the countenance flushed. The tone of the voice is peculiar in the first stage of labour. As the dilatation of the os uteri advances, the membranes enter into it during each pain, and its margin becomes softer and thinner, and the head of the child at the same time usually passes down through the brim, and occupies a considerable portion of the cavity of the pelvis. The os uteri becomes at last wholly effaced, and the head of the infant passes through it into the vagina. In most cases the membranes are now ruptured, if they have not previously given way, and the liquor amnii escapes. At other times the membranes are not only pressed into the vagina, but through its orifice upon the external parts, which they assist in dilating. After the rupture of the membranes a short interval of freedom from pain often ensues, and then they become much more acute and severe, and are accompanied with a strong desire to bear down. But there is often great irregularity in the strength, duration, and intervals of the pains. In some women, without any apparent cause, they disappear altogether for a considerable time, and several hours of sleep will follow. Even between the strong expelling pains in the second stage of labour some go to sleep, and the pains are absent for a considerable period. The duration of the first stage of labour varies very much in different cases. In some it is completed by a few pains; in others many hours of severe suffering is required to effect the expulsion of the head through the os uteri. The dilatation usually goes on much more slowly in first than in subsequent labours, and in persons advanced in life than in those who are under thirty years of age. This difference depends fully as much on the condition of the os uteri as on the strength of the uterine contractions. In some it is thin, soft, and dilatable at the commence-

ment of labour; in others thick, rigid, high up, and inclined backward or laterally.

In the second stage of labour the same phenomena are observed as in the first, but in a much more striking degree. The uterine contractions are much more violent, the patient fills the chest with air, closes the glottis to prevent its escape, involuntarily grasps any object near her, and forcibly bears down. The greater part of the head of the child is now in the cavity of the pelvis, and it is forced upon the perineum during each pain. The head most frequently lies obliquely or diagonally in the pelvis, with the occiput directed to the left acetabulum, and the forehead to the right sacro-iliac symphysis, the vertex being the most dependent part. When the membranes are ruptured, the pressure upon the head, during the pain, causes the integuments to become wrinkled, the parietal bones overlap one another, and, if the external parts are rigid and the labour is protracted, a tumor is formed under the scalp from blood being effused into the loose cellular membrane between the bones and integuments. At each succeeding pain the head presses against the parts at the outlet of the pelvis, and pushes them before it. The parts are gradually dilated, and, the head turning slightly round, the occiput is forced out between the labia. The perineum is carried forward by the pressure of the head, and becomes thin and distended. When the pain subsides the head recedes, and, the distension of the perineum being removed, the external parts resume their natural appearances. On the return of pain the head is forced still lower down, the perineum is again put upon the stretch, and to a still greater degree. The anus projects, dilates, and the contents of the rectum escape. The sufferings endured at this period are usually most intense, and the patient expresses the acuteness of her pangs by loud cries, sufficient, sometimes, to make the ears ring, or by deep, stifled, or suppressed groans. If we may judge from appearances, the suffering endured in some cases of labour is equal to what is experienced by those individuals who undergo severe surgical operations, or have the most violent cramps in muscular parts. In other cases the pain endured is trifling, and of such short duration that it is soon forgotten. At last, the head of the child, greatly compressed and swollen if it is a first labour, and there is much resistance at the outlet of the pelvis, is partially forced through the external parts, and does not recede when the pains go off. There is then usually in no long time a succession of strong expelling pain experienced, accompanied with involuntary efforts to bear down, by which the perineum is stretched to the greatest degree; at last it slides back on--

to descend through the brim and cavity to the outlet of the pelvis, and begin to press upon the external parts, before the contraction of the os uteri has been effected.

FIG. 1 represents the progress of the first stage of labour.

For several days before labour supervenes there are often certain symptoms observed which have been called the precursory or premonitory symptoms of labour. The first and most striking of these is a subsidence or sinking down of the uterus. The epigastric region, in consequence of this, becomes less distended, respiration is performed with greater ease, and the patient feels herself more comfortable, and more disposed and able to exert herself than she had been for some time before. This sinking down of the uterus is not from a mechanical cause, but from relaxation of the parts, and is often observed in the lower animals before parturition.

A sensation of weight in the inferior part of the pelvis and in the region of the uterus, and irritation of the bladder and rectum, often accompany the subsidence of the uterus. Not only do the parts become soft and relaxed, but in some women, before any

pains are experienced, much mucus is discharged from the vagina, and the cervix uteri becomes soft and relaxed, and the os uteri dilated. In some women, a week or more before labour supervenes, the patient is afflicted with sleepless nights, and the uterus is very irritable. Some women experience uterine contractions, and a few are afflicted with ruptured blood vessels. These pains are often attended with a sense of regularity, and are then slight, gradually increasing in frequency and intensity, and finally becoming stronger. In some women the os uteri is open

*On the Symptoms and Treatment of
Natural Labours.*

WHEN the foetus has completed the period of its existence in the uterus, it can live no longer in the same condition, and the great nervous and muscular structures of the organ, which have lain dormant during pregnancy, are suddenly roused into action in consequence of the stimulus imparted to them by the mature foetus, and the whole contents of the uterus are expelled. This process, which is always attended with pain and danger, is called *labour*, *delivery*, or *parturition*; all the varieties and complications of which have been arranged by Smellie and Denman in a regular systematic manner, under the four following heads:—

1. *Natural labour*, in which the head of the foetus presents or comes first; and the delivery is accomplished in twenty-four hours, by the natural contractions of the uterus and the assistance commonly given.

2. *Lingering, tedious, protracted, and difficult labour*, in which the head of the foetus likewise presents, but the labour continues upwards of twenty-four hours, and some unusual assistance is required. Irregular uterine action, nervous exhaustion, rigidity of the parts, cicatrices of the vagina, tumors of various kinds within the pelvis, and distortion of the pelvis, and unfavourable position, or unusual size of the foetal head, are the most common causes of

the difficulty experienced in the cases referred to this class, and which terminate either without manual or instrumental assistance after unusual suffering, or by the employment of the forceps or perforator.

3. *Preternatural labour*, where the nates, the inferior or superior extremities, present; or the umbilical cord is prolapsed; or there is a plurality of children.

4. *Complicated labour*, in which some dangerous accident occurs, unconnected with the presentation of the foetus: as uterine hæmorrhage, retention of the placenta, inversion or rupture of the uterus, puerperal convulsions.

This classification of labours is both natural and artificial; and for all practical purposes it is the best which has yet been proposed.

1. *Of the Symptoms and Treatment of
Natural Labour.*

In natural labour the head of the foetus presents, and the delivery is generally completed in twenty-four hours, and no artificial assistance is required. In every case the os uteri, vagina, and external parts, are dilated, the membranes ruptured, the child expelled, and the placenta and membranes separated and forced from the uterus. The dilatation of the os uteri, rupture of the membranes, and escape of the liquor amnii, take place in the first stage of labour. When the os uteri is fully dilated, and the head has passed through the os uteri, the first stage of labour is completed. The entire expulsion of the head, trunk, and extremities of the child, is effected in the second stage of labour; and in the third stage the placenta and membranes are detached from the inner surface of the uterus, and completely expelled both from the uterus and vagina. In the greater number of cases, before the first stage of labour has been fully completed the second has commenced and made some progress; and it is not unusual for the head

FIG. 1 represents the progress of the first stage of labour.

For several days before labour supervenes there are often certain symptoms observed which have been called the precursory or premonitory symptoms of labour. The first and most striking of these is a subsidence or sinking down of the uterus. The epigastric region, in consequence of this, becomes less distended, respiration is performed with greater ease, and the patient feels herself more comfortable, and more disposed and able to exert herself than she had been for some time before. This sinking down of the uterus is not from a mechanical cause, but from relaxation of the parts, and is often observed in the lower animals before parturition.

A sensation of weight in the inferior part of the pelvis and in the region of the uterus, and irritation of the bladder and rectum, often accompany this subsidence of the uterus. Not only do the parts become soft and relaxed, but in some women, before any

pains of labour are experienced, there is a mucous discharge from the vagina tinged with blood, arising from the dilatation of the orifice of the uterus, and the separation of the membranes. Some women suffer for a week or more before labour begins from sleeplessness at night, irregular pains about the uterus, and a peculiar nervous irritability. Some have at the first a sharp pain or uterine contraction, in a few hours another, and a few more after long intervals; whilst in others without pains the membranes are ruptured, and the liquor amnii escapes. These pains are sometimes experienced fifteen or twenty hours before the commencement of regular uterine action. They are then slight, produce little effect upon the constitution, and come at intervals of a quarter or half an hour, the intervals gradually becoming shorter, and the uterine contractions stronger. During these periodical pains the os uteri is opened, and its margin

becomes tense and stretched, and a slight degree of pressure is felt on the extremity of the finger, if an examination be made. As soon as the pain or uterine contraction subsides, this state of tension or stretching of the lips of the orifice of the uterus ceases, and the orifice itself again closes. The membranes are put upon the stretch also during the pains; but at first they do not protrude through the orifice. Gradually these pains, which are often called cutting or grinding, become more and more severe, continue longer, recur at shorter intervals, and leave a certain degree of uneasiness when they are absent; and each pain is sometimes preceded by a slight tremor or shivering; and sickness, vomiting, restlessness, impatience, and despondency, are often present during the whole of the first stage of labour. The action of the heart and arteries becomes increased, the skin hot, and the countenance flushed. The tone of the voice is peculiar in the first stage of labour. As the dilatation of the os uteri advances, the membranes enter into it during each pain, and its margin becomes softer and thinner, and the head of the child at the same time usually passes down through the brim, and occupies a considerable portion of the cavity of the pelvis. The os uteri becomes at last wholly effaced, and the head of the infant passes through it into the vagina. In most cases the membranes are now ruptured, if they have not previously given way, and the liquor amnii escapes. At other times the membranes are not only pressed into the vagina, but through its orifice upon the external parts, which they assist in dilating. After the rupture of the membranes a short interval of freedom from pain often ensues, and then they become much more acute and severe, and are accompanied with a strong desire to bear down. But there is often great irregularity in the strength, duration, and intervals of the pains. In some women, without any apparent cause, they disappear altogether for a considerable time, and several hours of sleep will follow. Even between the strong expelling pains in the second stage of labour some go to sleep, and the pains are absent for a considerable period. The duration of the first stage of labour varies very much in different cases. In some it is completed by a few pains; in others many hours of severe suffering is required to effect the expulsion of the head through the os uteri. The dilatation usually goes on much more slowly in first than in subsequent labours, and in persons advanced in life than in those who are under thirty years of age. This difference depends fully as much on the condition of the os uteri as on the strength of the uterine contractions. In some it is thin, soft, and dilatable at the commence-

ment of labour; in others thick, rigid, high up, and inclined backward or laterally.

In the second stage of labour the same phenomena are observed as in the first, but in a much more striking degree. The uterine contractions are much more violent, the patient fills the chest with air, closes the glottis to prevent its escape, involuntarily grasps any object near her, and forcibly bears down. The greater part of the head of the child is now in the cavity of the pelvis, and it is forced upon the perineum during each pain. The head most frequently lies obliquely or diagonally in the pelvis, with the occiput directed to the left acetabulum, and the forehead to the right sacro-iliac symphysis, the vertex being the most dependent part. When the membranes are ruptured, the pressure upon the head, during the pain, causes the integuments to become wrinkled, the parietal bones overlap one another, and, if the external parts are rigid and the labour is protracted, a tumor is formed under the scalp from blood being effused into the loose cellular membrane between the bones and integuments. At each succeeding pain the head presses against the parts at the outlet of the pelvis, and pushes them before it. The parts are gradually dilated, and, the head turning slightly round, the occiput is forced out between the labia. The perineum is carried forward by the pressure of the head, and becomes thin and distended. When the pain subsides the head recedes, and, the distension of the perineum being removed, the external parts resume their natural appearances. On the return of pain the head is forced still lower down, the perineum is again put upon the stretch, and to a still greater degree. The anus projects, dilates, and the contents of the rectum escape. The sufferings endured at this period are usually most intense, and the patient expresses the acuteness of her pangs by loud cries, sufficient, sometimes, to make the ears ring, or by deep, stifled, or suppressed groans. If we may judge from appearances, the suffering endured in some cases of labour is equal to what is experienced by those individuals who undergo severe surgical operations, or have the most violent cramps in muscular parts. In other cases the pain endured is trifling, and of such short duration that it is soon forgotten. At last, the head of the child, greatly compressed and swollen if it is a first labour, and there is much resistance at the outlet of the pelvis, is partially forced through the external parts, and does not recede when the pains go off. There is then usually in no long time a succession of strong expelling pain experienced, accompanied with involuntary efforts to bear down, by which the perineum is stretched to the greatest degree; at last it slides back over

the forehead and face of the child, and allows the whole head to escape. The time required for the dilatation of the perineum varies extremely in different cases: in first labours the head often presses upon it for several hours before this is effected, while in other cases only a few pains are required.

After the expulsion of the head, if the mucus in the mouth be cleared away, respiration soon commences, and the child goes on breathing regularly until another pain is experienced which expels the shoulders and body of the child through the outlet of the pelvis. At other times, and more generally, there is an interval of a minute or two, or still longer, between the pains, and when the

uterine contractions are renewed, the occiput usually becomes inclined to the left thigh of the mother, while the chin is turned to the opposite side. The shoulders then pass out of the pelvis, one under the arch of the pubes, and the other along the hollow of the sacrum, during which time the perineum is often again so much stretched as to be in danger of laceration. The transition is sudden from a state of the most intense suffering and anxiety to one of freedom from almost all pain, and the patient is left in a state of great excitement or exhaustion, with a rapid pulse, flushed countenance, and profuse perspiration over the whole body.

FIG. 2 represents the first stage of labour completed.

After a longer or shorter interval the uterus again contracts and expels the placenta, foetal membranes, and the coagula of blood formed within its cavity. In general the placenta is only partially or not at all detached from the uterus before the birth of the child. The same pain which expelled the child sometimes expels the placenta, but more frequently several minutes elapse, and sometimes half an hour or longer, before the contractions of the uterus are renewed, and the placenta descends through the orifice

into the vagina. If slight traction be made upon the cord downward and backward, a few pains are usually sufficient for the entire exclusion of the placenta and membranes.

If no assistance is given the uterus usually moulds the after-birth into a cylindrical form, and gradually forces it through the orifice into the dilated vagina, where it may remain a considerable period, until its presence excites the action of the diaphragm and abdominal muscles. Blood in greater or smaller quantity, fluid and coagulated,

continues for some hours to flow from the parts. The uterus, after it has been emptied of its contents, and has properly contracted, forms a round hard tumor like a cricket-ball in the hypogastrium. It often, however, for several hours, or even longer in women who have had many children, alternately contracts and relaxes, and, if the labour is protracted, it is painful on pressure, and prone to inflammation. In the course of a few days the sanguineous fluid which flowed from the exposed vessels of the uterus where the placenta had adhered assumes a greenish hue, and, at a later period, it has sometimes a milky or purulent appearance, and has a peculiar odour. This discharge from the uterus after delivery, called the lochial discharge, does not usually cease altogether until the uterus has contracted greatly and become much reduced in volume by the absorption of its coats, bloodvessels, and nerves. The uterus is much more rapidly absorbed in some women than in others, and this chiefly depends on the previous state of the patient's health, and the nature of the labour. In some women the pulse returns to the natural standard, and the exhaustion disappears quickly; in others, without any disease, the pulse continues rapid for several days, with considerable general febrile excitement. The secretion of milk occasionally commences immediately after delivery, but generally not till the second or third day. Such is a very general description of the phenomena most frequently observed in the progress of natural labours, and I now proceed to consider the treatment required in their different stages.

Treatment of Natural Labour.

The first circumstance to be attended to, when we have been engaged to take charge of a patient in her confinement, is that when sent for we are to proceed as expeditiously as possible to her assistance. We are frequently summoned at the very commencement of labour, or when the pains experienced are false or spurious, but this affords no ground for unnecessary delay in any case, for the whole process of delivery is not unfrequently completed in a short space of time, and with a few pains, and if we are not present fatal accidents may occur. Where the superior extremities present, or the umbilical cord surrounds the neck of the infant, or uterine hæmorrhage occurs, the favourable opportunity for operating may be lost, and the mother and child both sacrificed by unnecessary delay on the part of the medical attendant. Independent of the actual good we may do by immediately proceeding to the assistance of patients when summoned, their confidence in us is deservedly increased by a proper display of activity on our part, and by shewing that we sympathise with them in their sufferings, and

are resolved to do whatever lies in our power to avert the danger to which they are exposed. It is far from my wish to recommend you to practise any unworthy art, to affect an interest in their welfare which you do not feel, to gain the confidence and esteem of your patients; but I would urge you to employ all proper means to acquire their confidence, for without it you will find that it is impossible to conduct any case of midwifery to a satisfactory termination.

Though we should proceed without loss of time to the assistance of our patients in labour, yet we shall do harm if we propose immediately, in an abrupt manner, to ascertain the progress of the labour by an internal examination. No impatience ought to be manifested, or any inquiries made respecting the state of the different functions which could possibly offend their delicacy. No woman's feelings can be hurt by inquiring when the pains commenced—if they came on spontaneously—how often they return—how long they continue—if they begin in the back and come round to the front of the abdomen—and if they are accompanied with shivering and sickness, or a sensation of bearing down. By the answers given to these inquiries, and by the appearance of the countenance during the pains, we are sometimes able to form a tolerably correct judgment of the state of the case, though we cannot be absolutely certain that labour has actually commenced, and can give no positive opinion on the subject until we have been permitted to ascertain the state of the os uteri, or to take a pain, as nurses express it. However strong the pains may be, however regular in their recurrence, they may be false or spurious pains, and we cannot determine their true character if the patient does not allow us to make the proper investigation. Where it is a first child, and the patient feels an unusual dread of an internal examination, the hand may be applied to the abdomen to feel if the uterus becomes hard during a pain, and if so there is the greatest probability that labour has commenced. But, under such circumstances, until the pains have continued so long, and have occurred so frequently and with such force as to lead us to believe that the os uteri is considerably dilated, it is better, perhaps, to wait for a few hours to observe the progress of the symptoms than to urge the patient to submit to an immediate examination. Indeed, the proposal to ascertain the state of the case must not be made directly to the patient, but to the nurse, who, if experienced, will only require a hint, and will find no difficulty in obtaining the requisite consent; every woman being naturally anxious at the commencement of labour to know if she is safe, and if the infant is coming in the usual way. When the con-

forehead and face of the child, and allows the whole head to escape. The time required for the dilatation of the perineum varies exceedingly in different cases: in first labours the head often presses upon it for several minutes before this is effected, while in other cases only a few pains are required.

After the expulsion of the head, if the mouth is in the mouth be cleared away, respiration soon commences, and the child goes on breathing regularly until another pain is perceived which expels the shoulders and the rest of the child through the outlet of the vagina. At other times, and more generally, there is an interval of a minute or two, or still longer, between the pains, and when the

uterine contractions are renewed, the occiput usually becomes inclined to the left thigh of the mother, while the chin is turned to the opposite side. The shoulders then pass out of the pelvis, one under the arch of the pubes, and the other along the hollow of the sacrum, during which time the perineum is often again so much stretched as to be in danger of laceration. The transition is sudden from a state of the most intense suffering and anxiety to one of freedom from almost all pain, and the patient is left in a state of great excitement or exhaustion, with a rapid pulse, flushed countenance, and profuse perspiration over the whole body.

FIG. 2 represents the first stage of labour completed.

After a longer or shorter interval the uterus again contracts and expels the placenta, fetal membranes, and the coagula of blood formed within its cavity. In general the placenta is only partially or not at all expelled from the uterus before the birth of the child. The same pain which expelled the child sometimes expels the placenta, but more frequently several minutes elapse, sometimes half an hour or longer, before the contractions of the uterus are renewed, and the placenta descends through the orifice

into the vagina. If slight traction be made upon the cord downward and backward, a few pains are usually sufficient for the entire exclusion of the placenta and membranes.

If no assistance is given the uterus usually moulds the after-birth into a cylindrical form, and gradually forces it through the orifice into the dilated vagina, where it may remain a considerable period, until its presence excites the action of the diaphragm and abdominal muscles. Blood in greater or smaller quantity, fluid and coagulated,

continues for some hours to flow from the parts. The uterus, after it has been emptied of its contents, and has properly contracted, forms a round hard tumor like a cricket-ball in the hypogastrium. It often, however, for several hours, or even longer in women who have had many children, alternately contracts and relaxes, and, if the labour is protracted, it is painful on pressure, and prone to inflammation. In the course of a few days the sanguineous fluid which flowed from the exposed vessels of the uterus where the placenta had adhered assumes a greenish hue, and, at a later period, it has sometimes a milky or purulent appearance, and has a peculiar odour. This discharge from the uterus after delivery, called the lochial discharge, does not usually cease altogether until the uterus has contracted greatly and become much reduced in volume by the absorption of its coats, bloodvessels, and nerves. The uterus is much more rapidly absorbed in some women than in others, and this chiefly depends on the previous state of the patient's health, and the nature of the labour. In some women the pulse returns to the natural standard, and the exhaustion disappears quickly; in others, without any disease, the pulse continues rapid for several days, with considerable general febrile excitement. The secretion of milk occasionally commences immediately after delivery, but generally not till the second or third day. Such is a very general description of the phenomena most frequently observed in the progress of natural labours, and I now proceed to consider the treatment required in their different stages.

Treatment of Natural Labour.

The first circumstance to be attended to, when we have been engaged to take charge of a patient in her confinement, is that when sent for we are to proceed as expeditiously as possible to her assistance. We are frequently summoned at the very commencement of labour, or when the pains experienced are false or spurious, but this affords no ground for unnecessary delay in any case, for the whole process of delivery is not unfrequently completed in a short space of time, and with a few pains, and if we are not present fatal accidents may occur. Where the superior extremities present, or the umbilical cord surrounds the neck of the infant, or uterine hæmorrhage occurs, the favourable opportunity for operating may be lost, and the mother and child both sacrificed by unnecessary delay on the part of the medical attendant. Independent of the actual good we may do by immediately proceeding to the assistance of patients when summoned, their confidence in us is deservedly increased by a proper display of activity on our part, and by shewing that we sympathise with them in their sufferings, and

are resolved to do whatever lies in our power to avert the danger to which they are exposed. It is far from my wish to recommend you to practise any unworthy art, to affect an interest in their welfare which you do not feel, to gain the confidence and esteem of your patients; but I would urge you to employ all proper means to acquire their confidence, for without it you will find that it is impossible to conduct any case of midwifery to a satisfactory termination.

Though we should proceed without loss of time to the assistance of our patients in labour, yet we shall do harm if we propose immediately, in an abrupt manner, to ascertain the progress of the labour by an internal examination. No impatience ought to be manifested, or any inquiries made respecting the state of the different functions which could possibly offend their delicacy. No woman's feelings can be hurt by inquiring when the pains commenced—if they came on spontaneously—how often they return—how long they continue—if they begin in the back and come round to the front of the abdomen—and if they are accompanied with shivering and sickness, or a sensation of bearing down. By the answers given to these inquiries, and by the appearance of the countenance during the pains, we are sometimes able to form a tolerably correct judgment of the state of the case, though we cannot be absolutely certain that labour has actually commenced, and can give no positive opinion on the subject until we have been permitted to ascertain the state of the os uteri, or to take a pain, as nurses express it. However strong the pains may be, however regular in their recurrence, they may be false or spurious pains, and we cannot determine their true character if the patient does not allow us to make the proper investigation. Where it is a first child, and the patient feels an unusual dread of an internal examination, the hand may be applied to the abdomen to feel if the uterus becomes hard during a pain, and if so there is the greatest probability that labour has commenced. But, under such circumstances, until the pains have continued so long, and have occurred so frequently and with such force as to lead us to believe that the os uteri is considerably dilated, it is better, perhaps, to wait for a few hours to observe the progress of the symptoms than to urge the patient to submit to an immediate examination. Indeed, the proposal to ascertain the state of the case must not be made directly to the patient, but to the nurse, who, if experienced, will only require a hint, and will find no difficulty in obtaining the requisite consent; every woman being naturally anxious at the commencement of labour to know if she is safe, and if the infant is coming in the usual way. When the con-

sent of the patient has been obtained, let her lie down near the edge or foot of the bed, on her left side, under the sheet or coverlet, with the knees drawn up to the abdomen, and when a pain comes on, let the fore finger of the right hand, covered with cold cream, lard, soap, or some other unctuous matter, be gently passed from the anus along the perinæum into the vagina, and forward along its posterior surface, as far as the finger can reach. The point should then be drawn forward to the centre of the brim of the pelvis, where the os uteri is most frequently situated, or a little behind this, at the commencement of labour. You cannot fail to reach the os uteri if the finger be passed up along the posterior wall of the vagina, and the point of it be brought forward towards the symphysis pubis. While the pain continues, the most careful examination should be made to ascertain the degree to which the orifice is dilated, the effect produced upon it by the pain, and whether it is thin, soft, and yielding, and low in the pelvis, or high up, thick, rigid, and unyielding. During the pain, we have to ascertain whether the labour has commenced, and if so, the extent to which the os uteri is dilated, and from its condition endeavour to determine the probable duration of the labour. When the pain has subsided, and the os uteri and membranes have collapsed, and not before, the finger is to be passed very cautiously within the orifice, to discover whether the head of the child presents. The head is usually recognised without difficulty by its globular shape, the peculiar hardness of the parietal bones, and by the sutures. If the finger touches the sagittal suture, midway between the fontanelles, the edges of the parietal bones will be distinctly felt through the membranes. If you feel the hard edges of the parietal bones, you can have no doubt about the presentation, although neither fontanelle be touched. In no case is it necessary or proper at the commencement of the labour, before the membranes are ruptured, and the first stage completed, to endeavour to discover in what position the head of the child is placed relatively to the pelvis of the mother; it is enough to know with absolute certainty that the head presents; and this information should be possessed in every case; no doubt should be left on the subject, before the finger be withdrawn. Having ascertained that the pains are those of labour, and that the head presents, we have obtained all the knowledge that can ever be of use in practice. Any attempt to determine in which of the numerous positions described by some authors the head is placed at the brim of the pelvis, would only endanger the rupture of the membranes, and disturb the regular order observed by nature in the process. I am

greatly at a loss to discover what benefit could result from knowing during the first stage of labour, provided you can touch the vertex with the point of the finger, in which of the six or eight positions of Baudelocque, and other foreign authors, the head is placed. The importance attached by some writers to a knowledge of these positions, some of which are wholly imaginary, has probably arisen from the dangerous practice of employing the long forceps before the os uteri is fully dilated, and before the head has passed into the cavity of the pelvis. At this early stage of labour no instrument of this description can be safely used, and if the operation of turning the child were required, the position of the head would have no influence upon the method we would adopt in turning the child. Be sure that the head presents before you state this to the nurse or patient, for they will not soon forget your mistake if it should turn out to be a case of nates presentation.

In some cases where the head presents, it remains so high up, even when the first stage of labour is considerably advanced, that the finger cannot reach it without endangering the rupture of the membranes. Here the patient should be kept in the horizontal position, till the first stage of labour is nearly completed, and the presentation ascertained.

When it is the first labour, and the os uteri is high up in the pelvis, rigid, and little dilated, and the pains are irregular and produce little effect upon it, we infer that many hours will elapse before the labour is completed. As sudden and unexpected changes, however, often occur in the progress of labour, it is necessary to be extremely cautious, both in forming and delivering an opinion respecting its duration in every case. Even when the os uteri is widely dilated, its margin thin and soft, and the pains strong and regular, circumstances which could not have been foreseen may occur to retard delivery many hours beyond the time we expected. The assurance that the labour is natural, that the child is coming as it ought to do, that it is not a cross birth, which all women dread so much, and that there is every reason to expect in due time a successful termination of the labour by the natural efforts, is sufficient to satisfy the mind of every woman possessed of ordinary fortitude and intelligence. But there are some resolute enough in ordinary circumstances whose courage leaves them entirely during labour, and who require not only to be assured again and again that there is no danger, but to be convinced, by our cheerful and composed demeanour, that such is the fact.

I ought to have stated before, that if, on making an internal examination, we find no

change produced on the os uteri during the pains, we conclude that the labour has not commenced, and endeavour to discover and remove the cause of the irritation. False or spurious pains are usually vague and irregular, and never cease entirely. They often follow strong exercise, or fatigue from walking, and irregularities of diet, and occur before the full period. There is sometimes tenderness of the uterine region, and febrile excitement. They are to be relieved by opiates, warm fomentations, cathartics, and bleeding, according to the cause on which they depend.

During the first stage of labour the proper arrangements in the dress of the patient, the bed, and apartment, should be made for delivery. The stays, and every thing that can compress the body during the strong muscular efforts, should be removed, and a night-wrapper or loose dressing-gown put on. The mattress should be laid over the feather-bed; and over the dressed sheep's skin or water-proof cloth a blanket should be laid, and this covered by a folded sheet. According to the temperature of the atmosphere at the time, a blanket or coverlet should be placed over the patient when she lies down. The feet are usually pressed against one of the bed-posts during the pains, as she lies on the left side, and a long towel fixed to the other or foot of the bed, on which she can pull when the uterine action is strong. The apartment should be kept moderately warm, and well ventilated during the whole period of labour; and the food and drink should consist of tea, gruel, coffee, barley-water, toast and water, and other diluents. It is only when labour is protracted, and exhaustion takes place, that broth or beef-tea is required, and that a little wine and water, or brandy and water, should be given. If the bowels are confined when labour begins, give a sufficient dose of castor oil, or let a stimulating enema be exhibited. Until the first stage of labour is nearly completed, the patient should be allowed to sit up, to lie down, or walk about and change her position, as she may feel inclined. Even in the second stage of labour, if it is a first child, and the parts at the outlet of the pelvis are rigid, it is often useful to keep the patient for a time out of the recumbent position. Nurses often request them to bear down in the first stage; but this exhausts the strength, and voluntary exertions should never be made at any period of labour. The circumstances of each case will enable us to judge whether it is requisite for us to remain in constant attendance, or if we may with safety absent ourselves altogether for a few hours, and attend to other professional business. Our constant presence in the apartment is rather injurious than beneficial in most cases until

the first stage of labour is nearly completed, and the pains are strong and frequent. If the labour is protracted, it is necessary from time to time, at intervals probably of two or three hours or longer, to repeat the internal examination, that its progress may be ascertained. Women are anxious to know that the labour is advancing, and they are aware that this can only be ascertained by an internal examination, which if properly conducted can neither excite inflammation of the vagina nor produce any other injurious effect; at least I have never seen inflammation of the vagina nor laceration of the perineum where I could fairly attribute them to this cause. It is scarcely necessary for me to point out to you the necessity of examining the hypogastrium from time to time, to be sure that there is no accumulation of urine taking place in the bladder. In all protracted cases there is no circumstance which requires greater attention than this, and the immediate employment of the catheter when the necessity for it arises.

It is always requisite to make a careful internal examination when the membranes burst and the liquor amnii begins to escape, as a loop of the navel-string may descend before the head, or an upper extremity accompany it. The membranes should not be ruptured artificially, and no attempt should be made to dilate the orifice of the uterus or the external parts, in ordinary circumstances. When the head of the child comes to press forcibly against the perineum, and it is greatly distended and in danger of being lacerated, the patient should then be placed upon the left side in bed, and should not quit that position for an instant. The left side is by far the most convenient position both for the patient and her medical attendant, and it is so not only in natural labour but in all cases where the forceps or perforator are to be employed, or the operation of turning performed. The palm of the right hand, with a soft napkin interposed, should be firmly applied over the centre of the perineum, and proper support given during the pains. In first labours, where the head is large and the perineum rigid, and the uterine contractions violent, the parts at the outlet of the pelvis are often extensively torn where this artificial support is not given effectually. Extensive laceration of the perineum very rarely occurs where the necessary assistance is afforded with the palm of the right hand placed over it, and strong counter pressure made during the pains. By counter pressure is meant, pressing the head forward to the symphysis pubis, and preventing the whole force of the uterine action being directed against the perineum. It is sometimes requisite to guard the perineum thus for several hours, and, where it is exposed to great danger, it

is useful occasionally to cover it with some unctuous matter, or still better, between the pains, to apply over it a large sponge soaked in hot water. Nothing should be interposed between the hand and perineum when it is in great danger of being torn. The right knee should be supported when the head is thus pressing upon the parts at the head of the pelvis, and the patient strongly urged to abstain from all voluntary efforts to bear down.

When the head has passed, clear away all the mucus in the mouth, that the child may breathe, and feel whether the umbilical cord surrounds the neck. If it does, and is not tight, the best practice is to leave it alone, or slide it up a little over the shoulders when a pain comes on, that they and the body may pass readily through the loop. I prefer doing this, or merely slackening it a little, to pulling the loop entirely over the head, which is sometimes done. If there is no pain to expel the trunk soon after the head is born, make firm pressure over the fundus uteri, and excite it to contract. The child should never be dragged into the world, but the uterus should always be made to expel it: even if several minutes should elapse without any pain occurring, I would not pull the child forward, but wait until it was forced into the world by the action of the uterus. It is of the greatest consequence that the uterus should not be suddenly emptied of its contents. When the shoulders are passing, the perineum should again be supported: then draw the child into the light, and if it has breathed freely and vigorously, apply a good strong ligature very firmly around the cord, about two fingers breadth from the navel. This ligature should be applied with as much care as around a large divided artery, and to make it perfectly secure pass it twice round the cord, and tie it firmly. Apply another ligature an inch or two nearer the placenta, and divide the funis between the ligatures with a pair of scissors, put the child in the flannel receiver, and give it to the nurse. If the respiration is not readily established, recourse must be had in the first instance, before applying the ligatures, to the dashing or sprinkling of cold water over the face and chest, rubbing the chest with brandy, and the application of stimulants to the nostrils. Immersion of the child in warm water, and inflating the lungs, should be employed, and our efforts to excite respiration should not cease until the pulsations in the heart and funis have entirely ceased for some minutes. When this is the case all our efforts to restore animation will be useless.

Next ascertain, by applying the hand over the abdomen, if there be another child within the uterus. If there be a second child the fundus of the uterus will still be

in the epigastrium; it will be large and hard, and some part of the child distinctly felt. If there is a doubt about the presence of a second child within the uterus, examine internally, and the second bag of membranes and presenting part, if there are twins, will be distinctly felt. If this could not be ascertained by passing two fingers of the right hand along the cord of the first child, it would be justifiable to introduce the whole hand into the vagina.

I have several times been sent for to deliver a second child when there was nothing within the uterus but an unusually large placenta. When there is not a second child, the fundus uteri is usually felt nearly as low as the umbilicus, and it is greatly reduced in size, and has none of the irregular hardness which is always felt in cases of twins.

The temporary binder, to which I attach the greatest importance, should now be applied firmly around the abdomen. In all cases of labour, immediately after the birth of the child, a broad bandage should be applied around the body. A broad towel or napkin is often employed for this purpose, and, without raising the patient, it may be passed under her, and spread out so as to surround the whole pelvis and abdomen, and firmly fixed with tapes or strong pins. It should be so tightly applied around the lower part of the abdomen as to occasion a slight degree of uneasiness. The firm equal pressure of the binder or bandage over the uterus causes it to contract in a regular manner, and diminishes greatly the risk of syncope, retained placenta, and hæmorrhage. Some have attributed inflammation of the uterus after delivery, and prolapsus, and a great many other evil consequences, to the temporary binder, but, as you may suppose, without the slightest proof or foundation. Some practitioners apply a binder exterior to the clothes at the commencement of labour, and tighten it as the process advances. Even in the eighth month of pregnancy, where there is great relaxation of the abdominal parietes, it might sometimes be proper to give gentle support to the pendulous abdomen with a bandage.

Our great object now is to make the uterus permanently contract, to detach and expel the placenta, and prevent hæmorrhage. For this purpose, if the labour has been tedious, and there is much exhaustion, some stimulant, as a little wine and water, or brandy and water, should be administered; and over the binder, if the uterus is relaxed, and indisposed to contract, the hand should be placed, and firm pressure made. When a pain is felt, slight traction in the direction of the axis of the pelvis, downward and backward, should be made upon the cord, to promote the separation of the placenta from

the uterus. By compressing and squeezing the fundus uteri, and gently pulling from time to time upon the cord, the placenta usually descends, and passes through the os uteri into the vagina, in the course of a quarter of an hour, or twenty minutes, or half an hour, after the birth of the child. More anxiety is often felt by us during this period than during the whole of the previous stages of the labour, and not without good reason. In removing the placenta from the vagina, it is necessary to be very careful that the membranes are not torn away from its margin, and left behind. The best method of obviating this accident is slowly to turn the placenta round twice or thrice as we extract it, and if the membranes seem disposed to tear, as we gently draw them out, to seize them with a dry napkin, and very gradually remove them. The placenta may be retained beyond the usual period, by want of uterine action, by morbid adhesion to the uterus, and by premature contraction of the cervix. On whatever cause it depends there are no cases in which the placenta ought to be permitted to remain within the uterus beyond an hour after the birth of the child, and not so long if hæmorrhage takes place. That there may be no misunderstanding on this important practical point, I repeat, that I have never seen a case of retention of the placenta where any thing but mischief resulted from leaving it within the uterus beyond an hour after the expulsion of the child. If the binder has been applied, and pressure made over the fundus uteri, and traction upon the cord properly employed, and the placenta does not descend at the end of an hour, I would not advise you to give the ergot of rye, or to wait longer for its detachment and expulsion, but to put the cord upon the stretch with your left hand, and to introduce your right hand, in a conical form, through the vagina into the uterus, to spread out the fingers to the circumference of the placenta, and to press the mass slowly from the uterus if it still adheres, and to extract it. In the greater number of cases the placenta has been completely or partially detached from the uterus when this requires to be done.

When the placenta has come away, or been removed, make the patient dry and comfortable, by removing all the wet clothes, and applying warm napkins to the external parts, and around the pelvis, and giving her warm gruel, with a little wine or brandy, or some warm tea. As hæmorrhage may occur an hour or more after delivery, you should from time to time feel the pulse, enquire if the patient is faint, ascertain if the uterus is contracted, and if the discharge is not too great. It is a good rule to remain with every patient at least an hour after the expulsion of the placenta, and if there is faintness, and

a disposition to flooding, it is necessary to devote a much longer time to the case.

If severe after-pains soon commence, or if they have occasioned much suffering in former labours, it is useful to administer a draught, with 30 or 40 minims of the *Liquor Opii Sedativus*. I am an advocate for an opiate after delivery, to soothe the nervous system, if much excited by severe and protracted suffering. If opium be useful in tranquillising the system, and preserving it from febrile excitement and irritation after extensive wounds of the large cavities, surely it cannot but be beneficial after delivery, and it can do no harm, particularly if combined with a saline diaphoretic draught. Where a labour has been severe, and inflammation of the uterus is to be dreaded, it is not only useful to administer a sufficient quantity of an anodyne to quiet the system, but for a day or two to give small doses of Dover's powder to subdue irritation, and promote perspiration. It is beneficial, also, under such circumstances, to cover the hypogastrium with a warm poultice, or occasionally to apply warm fomentations.

Three or four hours ought in all cases to be allowed to pass, after the labour is concluded, before the patient is moved up in the bed, and has her clothes changed, and when this is being done by the nurse, she ought to make no exertion, or to quit the horizontal position. The apartment should be kept moderately warm, and free from all noise and excitement of every kind, and nothing should be given but gruel, tea, or barley water, for 48 or 60 hours, in the majority of cases.

With respect to the infant, it is necessary to see before quitting the house that it is not malformed, that the cord is properly secured, that it is not unnecessarily exposed to cold air, while being washed by the nurse, and that no improper food or medicine is administered. A small tea-spoonful of castor oil may be given to expel the meconium. A little warm milk and water or thin gruel is the only food that is required before applying the child to the breast, which should not be done for at least twelve hours after delivery. Every patient should be seen by her medical attendant within twenty-four hours after delivery, and if possible daily, at least for a week after. The danger of child-bearing may now almost be said to commence, for there are very many women who pass through the different stages of labour with impunity, who perish in the puerperal state. Inflammation of the uterus and its appendages is the cause of all the danger, and in the daily visits which you make this is the great point to which your attention should be directed. Pain, increased by pressure over the hypogastrium, suppression of the lochia and milk, rigors, headache, and

quick pulse, are the principal diagnostic symptoms. It most frequently commences on the second and third day after delivery, but sometimes within twenty-four hours.

At each daily visit pass the hand over the region of the uterus, press upon the fundus and over the situation of the uterine appendages, and you will sometimes detect uterine inflammation where the complaints of the patient and the statements of the nurse would have given you no reason to suspect its existence. Examine the state of the bladder, the pulse, tongue, lochial discharge, and mark the expression of the countenance, and never fail to inquire if there is milk in the breasts, and if the patient has had any coldness or shivering, or is suffering from headache. If the pulse continues several days after delivery 100 or 110 in the minute, and one or more of these symptoms are present, the patient is not safe.

It is of the utmost importance to form a correct diagnosis between after pains and uterine inflammation. Many women are lost in consequence of this mistake. Generally there are intervals of complete freedom from suffering in the irregular contractions of the uterus which follow delivery, without inflammation, and constitute after pains; they are relieved by pressure over the uterus—they gradually diminish in severity on the second and third days, and they are unaccompanied with rigors, fever, and headache, and the lochial discharge is not suppressed. But if you cannot satisfactorily establish the diagnosis between after-pains and inflammation of the uterus, I would take the least favourable view of the symptoms, and give the patient the benefit of a small general bleeding, or the application of leeches to the region of the uterus. I have seen many puerperal women lost for want of timely depletion; I never saw one suffer in consequence of a moderate quantity of blood being taken from the arm, or from the hypogastrium by leeches.

On the third morning after delivery it is necessary in most cases to administer a mild cathartic, castor-oil, or an aperient draught of senna, sulphate of magnesia and manna, should be given, and where the bowels have not been attended to before the labour, this should be done on the second morning. The diet of puerperal women during the first week should be the same as that allowed to persons who are convalescent from fever, or from severe acute diseases. Until the secretion of milk is established, nothing but gruel, tea, a little thin arrow-root, or panado, should be allowed. On the fourth day, if there is no pyrexia, and the child has taken the breast, and the milk flows freely, a little beef-tea or chicken broth may be given. This should be continued in all cases till the end of the first week, and even

at the end of that period, if the tongue is not clean, the pulse quiet, and the abdomen wholly free from tenderness on pressure, the patient should still be kept on low diet. After the ninth day in ordinary cases, some chicken or solid animal food may be allowed with a little wine and water, and after this the patient may gradually return to her accustomed diet.

These are all the observations which I consider it necessary to offer on the phenomena and treatment of natural labours. When I have described all the varieties of difficult, preternatural, and complicated labours, I shall endeavour to give you a full account of the pathology and treatment of the acute, inflammatory, and febrile diseases of puerperal women, and the other diseases which follow delivery.

LECTURES
ON THE
PHYSICAL AND PATHOLOGICAL
CHARACTERS OF URINARY
DEPOSITS,

Delivered at Guy's Hospital, London,

BY DR. GOLDING BIRD.

LECTURE V.

Carbonate of lime. Cause of ammoniacal urine. Presence of phosphates in urine. Solubility of phosphates in ammoniacal salts—in carbonic acid—deposited by boiling—mistaken for mucus—crystalline forms of. Phosphate of lime. Phosphatic urine—varieties of. Sources of phosphates—traced to vegetable ingesta—and destructive assimilation of nervous tissue.

GENTLEMEN — The next constituent of urinary deposit to which I have to direct your attention is one by no means of frequent occurrence, viz :

Carbonate of lime.

This salt, although a constant ingredient in the alkaline urine of graminivorous animals, never occurs in the urine of carnivora or of man; unless as the result of certain secondary changes, of which the most essential is the resolution of urea into carbonate of ammonia, and the consequent formation of carbonate of lime. You have not, I trust, forgotten the explanation I have given you of the probable formation of carbonate of ammonia from urea; the addition of water being sufficient to afford all the elements necessary for the production of the salt under consideration. So that urea may be regarded as carbonate of ammonia minus water, or a *carbonamide*. We know that the conversion into the carbonate takes place but slowly in healthy urine out of the body, and with still less

rapidity when this substance is dissolved in pure water. Still less frequently does this change take place whilst the urine is retained in the bladder. Under certain circumstances, however, especially where an excess of mucous matter is secreted, this substance acts the part of a ferment, induces a new arrangement of the elements of urea and water, and thus the urine is voided in an ammoniacal condition. Excepting, however, under certain circumstances of by no means constant occurrence, the vital endowments of the bladder are sufficient to preserve the urine from undergoing this change, even if a very considerable quantity of mucus be present. It is only, indeed, when the conservative powers of the nervous influence supplying the bladder become exhausted, that its contents become subject to the ordinary laws of chemistry. Thus, as has been long shewn by Dr. Prout and Sir Benjamin Brodie, blows on the back have a tendency to produce alkaline urine; a fact admitting of ready explanation, by the necessarily depressed condition of the nervous power of the bladder, resulting from the injury to the spine. Even in these cases, however, I doubt considerably whether the urine is by any means generally *secreted alkaline*. From the result of many cases which have occurred in this hospital I am induced to believe that the urine is secreted by the kidneys in the usual subacid condition, and that it becomes alkaline by the subsequent change which it undergoes in the bladder, when the vital endowments of the latter have become depressed, and the mucus acting as a ferment converts the urea into carbonate of ammonia. In confirmation of this view I have repeatedly observed that, in cases where the urine appeared alkaline, on emptying the bladder with a catheter it was found that the partly secreted urine was acid or neutral, and it was only after being retained for some time in the bladder that it presented alkaline properties.

Again, in cases of paraplegia, where the urine is often found to be alkaline, this state may be almost constantly traced to the inability of the patient to empty the bladder; and thus it is the *retained urine* which undergoes change; the freshly secreted portions being nearly natural. In the case of a woman labouring under complete paraplegia, whose urine was seldom voided, and was ropy, alkaline, and offensive, I washed out the bladder with warm water, and left an elastic catheter in the urethra, so that the urine might escape almost as soon as it reached the bladder. Under these circumstances the urine appeared clear, pale, and slightly acid, whilst that voided 24 hours before was dark, offensive, alkaline, and turbid not only from mucus, but from sediment, consisting of carbonate of lime and the earthy phosphates. The best and most satisfactory cases in which

the urine was secreted alkaline are those recorded by Dr. Graves, of Dublin; one of them was a case of adynamic typhus fever, in which an abundance of carbonate of ammonia existed in the urine, and a corresponding deficiency of urea and uric acid existed. *Pari passu* with the convalescence of the patient the carbonate of ammonia vanished, being replaced by an equivalent proportion of urea and uric acid. The second case was one of fatal general anasarca, following exposure to cold; here the urine was loaded with carbonate of ammonia, but neither urea nor albumen existed. After death the bladder appeared perfectly healthy.

Whilst I have thus endeavoured to explain to you the reasons which have induced me to regard the development of carbonate of lime as almost invariably secondary to changes which the urine undergoes in the bladder, I must confess that more information is required on this subject. I have never seen a deposit consisting entirely of carbonate of lime, but have not unfrequently met with it in small quantities in phosphatic deposits. We have, in our hospital museum, but a single specimen in which carbonate of lime occurs in any considerable quantity. It is, however, very remarkable, that an excellent and highly respected provincial surgeon, Mr. Smith, of Bristol, has met with many instances of calculi composed chiefly of this calcareous salt. Should such calculi be again met with, it will be extremely important to carefully examine the urine passed by the patients from whom they were removed. We may thus resolve the curious questions whether in certain states of health the urine is secreted alkaline, like that of herbivora, or whether such an alkaline condition is really secondary.

The next series of deposits that will engage our attention includes those which are composed of ingredients chiefly of inorganic origin. This class contains four varieties of deposits, viz. those composed of phosphate of lime, of triple phosphate, of a mixture of these salts, and of silicic acid. Although this division to a certain extent is practically necessary, yet in our consideration of them I shall explain to you the peculiarities of deposits consisting of phosphates generally, as they are accompanied by analogous phenomena.

Phosphatic Deposits.

You are aware that on an average 6.5 grains of phosphoric acid leave the system in the urine in the course of 24 hours. Although the particular state of combination in which this acid exists may admit of doubt, yet it is evident that a considerable portion of it exists in urine with lime, magnesia, and ammonia. The two latter bases very probably exist in the same combination, forming a

double salt; the ammonio-phosphate of magnesia, or triple phosphate, as it is termed.

If you add a very small quantity of ammonia to a large quantity of healthy urine the mixture becomes turbid from a deposit of the triple phosphates, mixed in all probability with phosphate of lime. On placing a drop of this turbid urine under the microscope, myriads of minute prisms of the triple salt, mixed with amorphous granules of the phosphates of lime, will be seen floating in the fluid. These readily disappear on the addition of a drop of almost any acid. As these earthy salts are insoluble in water, it is evident that they must be held in solution in the urine by the free acid which generally exists; this acid is either the phosphoric or lactic, or both. If from any cause the quantity of solvent acid falls below the necessary proportion, the earthy phosphates appear in the urine, forming a deposit. Hence, when the urine is alkaline, phosphatic deposits are necessary consequences. If urine be secreted with so small a proportion of acid as barely to redden litmus paper, a deposit of triple phosphates often occurs a few hours after emission; a phenomenon depending on the influence of the mucous matter present, which exciting a catalytic action like a ferment, induces the decomposition of urea, and the formation of carbonate of ammonia, which by neutralising the solvent acid, throws down the phosphates. The precipitation of the phosphates thus takes place in a manner analogous to that in which carbonate of lime is thrown down, the action being here limited to a neutralisation of a free acid: indeed, where phosphates of lime form the great bulk of a deposit, a certain portion of carbonate is generally present.

It is, however, by no means necessary for urine to be alkaline for a deposit of phosphates to exist; indeed, in the great majority of cases, urine which deposits the triple phosphate is acid at the time of emission, and often for long after. This may appear rather paradoxical, when we recollect the ready solubility of triple phosphate in a very weak acid; but admits of a ready explanation when the fact that a fluid may redden litmus, and still contain no uncombined acid, is borne in mind. Thus, a solution of hydrochlorate of ammonia will redden litmus paper, and yet it contains no free acid; and as this salt exists in the urine, it is quite possible that it may be one of the causes on which its acid reaction depends, where deposits of phosphates exist. It has been rendered very probable, by the interesting experiments of Dr. Rees, that this very salt may in some instances be really the solvent of the earthy phosphates, as they are to a certain extent soluble in solutions of sal-ammonia. These solutions

possess the very remarkable property, first pointed out by the excellent chemist to whom I have just referred, of becoming opaque by ebullition, from a deposition of a portion of the earthy salt. The very same phenomenon often occurs in urine which contains an excess of phosphates. Indeed, it is not unfrequent to meet with urine which does not contain any visible deposit, and yet on the application of heat appears to coagulate, not from the presence of albumen, but from the deposition of earthy phosphates. The addition of a drop of nitric acid immediately dissolves this deposit, and distinguishes it from albumen. A different explanation to this phenomenon has been offered by Dr. Hargrave Brett, and which undoubtedly is perfectly true in many cases, although the hypothesis of Dr. Rees is applicable to the greater number. Dr. Brett's explanation is founded on the solubility of phosphates in water impregnated with carbonic acid. It has been long known that carbonic acid frequently exists in a free state in the urine, and in a large number of specimens examined by Dr. Brett and myself we succeeded in readily isolating it. These experiments were made several years ago, in consequence of our having noticed some curious phenomena presented by the urine of a student of this hospital (since dead), a pupil of the late Mr. Bryant, of Kennington. This gentleman, in endeavouring to raise a heavy sack of Epsom salts, strained his back, and soon after fell into a state of marasmus, with occasional hectic, which ultimately exhausted him. During the last six months of his life he passed a very large quantity of pale acid urine, which by keeping soon became alkaline. This urine was limpid when first passed, but became opaque as soon as it had cooled, still, however, retaining its acidity, so that the deposition of the phosphates did not necessarily depend upon the development of an alkali. On warming the fresh urine an evolution of carbonic acid gas took place, accompanied by a deposition of phosphates. When the two portions of the fresh urine were placed as soon as passed in separate bottles, and left open, and the other closely corked, the urine contained in the latter remained transparent, and that in the former became opaque.

Whenever the triple phosphate occurs in the urine as a deposit, it is always found to be composed of crystals which are generally sharply defined, and extremely regular. You must, however, bear in mind that these crystals may exist in large quantities, and yet escape detection in consequence of their extreme transparency. In cases of this kind the deposit which forms by repose generally presents the appearance of a mere mucous cloud, and it is only distinguished from it by the addition of an acid, which immediately

dissolves it. On decanting such urine and placing the lower turbid portion in a watch-glass, the crystals may be detected by moving the latter near a lighted candle, when a series of glittering points will become visible from the reflection of the light from the facets of the minute prisms of triple salt. On placing the watch-glass under a microscope the crystals may be readily recognised. The depositions of the phosphates may become accelerated by warming the urine in the manner I explained to you when speaking of the oxalate of lime. The exact resemblance presented by the deposits of phosphates to mucous clouds is so very close that the most practised eye can scarcely distinguish between them; indeed, scarcely a week passes but I find myself completely at fault on attempting to distinguish between them by bare inspection. When phosphate of lime exists mixed with the triple salt, the deposit often remains for a long time diffused through the urine, so as to resemble rope-like masses of purulent mucus. Not only do deposits of phosphates resemble mucus and pus in physical appearances, but they frequently co-exist. Indeed, it is very frequent to find fine prisms of triple phosphate entangled in the meshes of the mucous cloud which forms by repose in all urine. When the triple phosphate co-exists with mucus or pus, the microscope will readily detect its presence.

Occasionally, where a small excess of the triple phosphate is present, it is found on the surface of the urine, forming a delicate iridescent scum or pellicle, reflecting coloured bands of light, like a thin layer of oil, or the surface of a soap-bubble.

When a considerable quantity of ammonia is added to urine, a deposit occurs from setting free a triple phosphate of magnesia, which differs from that to which I have just been alluding, in containing half an equivalent more of ammonia; it is in fact a *sesqui-basic*, or, as it is commonly termed, a bibasic triple phosphate of magnesia and ammonia. This is evidently formed by the ammonia playing a double part; it not only neutralises the solvent acid, but combines with the normal phosphate to form a basic salt. This can be readily distinguished from the neutral salt by its crystalline form, as it always presents the form of stellæ, generally six-rayed, often elegantly pinnated, in some cases presenting the appearance of foliaceous crystals resembling fern leaves; this variety, however, being almost always the result of decomposition, when the urine has been kept a long time.

This basic phosphate invariably, and I believe necessarily, exists with alkaline urine; it very rarely occurs in recent urine, and so far as I have had occasion to observe, is always a secondary product.

Before proceeding to explain the general properties of urine depositing phosphates, I would call your attention to these diagrams, exhibiting the crystalline forms of the phosphatic magnesian salts, as it is important you should be sufficiently familiar with them to enable you to recognise them.

A. *Prisms of neutral triple phosphates*.—These are always exceedingly well defined, the angles and edges of the crystals being remarkably sharp and perfect. The triangular prism is the form most frequently met with, but it presents every variety in its termination. These are sometimes merely truncated, often bevelled off, and not unfrequently the terminal edges are replaced by facets.

FIG. 16.

I scarcely know a more beautiful microscopic object than is afforded by a well-marked deposit of this salt. You will frequently be struck with the very different degrees of transparency presented by these crystals; sometimes they are so transparent as to resemble prisms of glass or crystal; at others presenting an enamel-like opacity, so that they can only be viewed as opaque objects. When preserved in balsam, they depolarise light very beautifully where the axes of the tourmalines or calc-spar are crossed in the polarising microscope.

B. *Simple stellæ of the neutral salt*.—These are in fact minute calculous concretions, and are generally composed of minute prisms cohering at one end, so as to represent simple stellæ. Not unfrequently they adhere so closely and so crowded as to resemble rosettes. I have repeatedly seen small prisms crystallized as one of the fine transparent hairs which are of frequent occurrence in urine. Indeed, if for the word *rhomboids* you substitute *prisms*, the account I have given you in a former lecture of the varieties of the compound crystals of uric acid will apply to the phosphatic magnesian salt, bearing in mind that the latter is invariably colourless, never presenting the yellow or orange hue of uric acid.

C. *Penniform crystals of neutral salt*.—This very elegant variety of the neutral magnesia phosphate has only lately fallen under my notice, and has not hitherto been de-

scribed. It presents the appearance of striated feather-like crystals,

FIG. 17.

two being generally connected so as to cause them to resemble a pair of wings. I cannot give any satisfactory explanation of the causes of this curious and elegant variety, or whether they differ in any way chemically from the prismatic form. The few specimens I have met with occurred in acid urine.

D. *Stella and foliaceous crystals of basic salt.*—This variety, as I have already told you, cannot generally be regarded in any other light than as a secondary product taking place out of the body. When rapidly

FIG. 18.

formed, we generally find this salt in the form of six-rayed stars, each ray being serrated, or irregularly crenate, often renuncinated, like the leaf of the taraxacum. This, however, presents several subordinate varieties, depending, in all probability, upon accidental circumstances. When this salt is more slowly formed, as on the surface of the urine of pregnancy, it presents large and broad foliaceous laminæ, often so thin and transparent as to escape notice altogether, especially if viewed in too strong a light. I have, indeed, often overlooked them until I illuminated the specimen under the microscope with pulverized light, when they started into view elegantly tinted with colours in which pink and green are the most prominent.

There are no definite microscopic characters by which phosphate of lime can be recognised in deposits; it always appears as a

mere amorphous cloud, made up of extremely minute particles, sometimes presenting a globular arrangement. In this form they are frequently found adhering to prisms of the triple salt, and their nature can be readily made out by the addition of a drop of very dilute hydrochloric acid, in which both phosphates readily dissolve, and by this property are at once distinguished from all organic globules, which are insoluble in that menstruum. These deposits are so readily recognisable with the assistance of the microscope, that it can scarcely be deemed necessary to have recourse to their chemical characters, which are often made out with extreme difficulty, from the small quantity of deposit we have in most cases to operate on. If any doubt should, however, remain regarding the nature of any deposit of this class, it may be sufficient to recollect that of all the deposits possessing a true crystalline form which have yet been examined, the triple phosphate is the only one which is soluble in acetic acid, and of all amorphous deposits, the phosphate of lime is the only one which does not disappear on the addition of liquor potassæ.

The urine, in cases where an excess of phosphates of either kind exists, differs in its physical character very materially. Certainly no general rule can be assigned for the colour, density, or quantity of the urine secreted in these cases, taking them in a mass; although I think there are certain facts connected with the presence of the phosphatic deposits which serve to connect the colour and quantity of the urine with the pathological conditions producing, or at least co-existing with them.

As a general rule, where copious phosphatic deposits, whether magnesian, calcareous, or both, exist for a considerable time, the urine is pale, often whey-like, and of low specific gravity. This is especially the case where organic lesion of the kidneys exists. On the other hand, when the deposits are of occasional occurrence, often disappearing and recurring in the course of a few days, the urine generally presents a deep amber colour, and is not only of high specific gravity, but often contains an excess of urea, and presents an iridescent pellicle on its surface by repose. This is especially the character of the phosphatic urine secreted under the influence of some forms of irritative dyspepsia, and where the phosphates themselves may be traced to mal-assimilation. Again, phosphatic urine may be met with varying from a pale whey-like hue to deep brown or greenish brown, exceedingly fetid, generally but not constantly alkaline, and loaded with dense ropy mucus, often tinged with blood, and in which large crystals of the triple phosphate and amorphous masses of phosphate of lime are entangled. This variety is almost always met with either under

the irritation of a calculus, or where disease of the mucous membrane of the bladder exists.

It was long ago remarked by Berzelius, that phosphatic deposits were often present in the urine passed in one part of the day, and absent in other specimens. I carefully watched a series of cases where the triple phosphate existed in the urine, with a view to determine the accuracy of this statement, and am convinced that the following may be assumed as a safe induction from these observations. *That where the presence of deposits of phosphates is independent of the irritation of a calculus, or of organic disease, it is most abundant in the urine passed in the evening (urine of digestion), and absent*

or replaced by uric acid, or urates, in the morning urine (urine of the blood), the urine being always of tolerably natural colour, never below, and often above the mean density. Where the presence of phosphatic salt depends on the irritation of a calculus, or of organic mischief in the urinary passages, the urine is pale and whey-like, of a density below the average, often considerably so, and the earthy deposit is nearly equally abundant in the night and morning urine.

I have arranged, in the table before you, the results of some of my observations on several specimens of urine yielding some copious deposits of triple phosphate, and unconnected with calculus or organic disease.

Urine depositing phosphates without organic disease.

Evening urine.				Morning urine.				Case.
Colour.	Density.	Action on litmus.	Deposit.	Colour.	Density.	Action on litmus.	Deposit	
Pale amber	1.029	Neutral.	Prisms of triple phosphates.	Dark amber.	1.031	Neutral.	Red urates.	Gouty dyspepsia.
Normal	1.028	Alkaline.	Ditto.	Normal.	1.025	Acid.	Ditto.	Ditto.
Pale	1.020	Neutral.	Ditto with phosphate of lime.	Pale.	1.025	Ditto.	Uric acid.	Ditto.
Pale	1.022	Neutral.	Nearly all phosphate of lime.	Normal.	1.025	Ditto.	Ditto.	Ditto.
Normal	1.028	Barely alkaline.	Prisms and stellæ of phosphate.	Ditto.	1.031	Neutral.	Ditto and scanty prisms of phosphate.	Dyspepsia of intemperance.
Amber	1.025	Acid.	Prisms of phosphate.	Ditto.	1.020	Acid.	None.	Dyspepsia following fatigue.
Amber	1.025	Acid.	Fine stellæ of triple salt.	Ditto.	1.020	Ditto.	Ditto.	Dysmenorrhœa.

In these examples you have an excellent illustration of the fact announced by Berzelius, that phosphates may be abundantly present in some specimens of urine and deficient in others passed within a few hours of the former. We must next investigate the

Cause of the excess of phosphate in the urine.

I shall not here direct your attention to the immediate cause as connected with the particular function involved, as this has been so well and so accurately explained by Dr. Prout in his elegant and valuable work on "Stomach and Urinary Diseases," that I should feel it quite unjustifiable to occupy your time further than to press you to peruse this excellent volume, unless I had far more information to add to what is there laid down

on this important subject, than I really possess. The question for me to take up in this place is the one which, as in the case of uric acid and urates, has been of late much neglected, especially by the disciples of Liebig—on the nature of the ultimate origin of phosphates in the urine. When we recollect that combinations of magnesia, lime, potass, and ammonia, exist in great abundance in the articles of food yielded by the vegetable kingdom, we at once discover a probable source of much of the phosphates in the urine, and, indeed, in other fluids and solids of the body. It is easy to prove that much more of the phosphatic salts are thus taken into the system than can possibly be got rid of by the urine, which as we have seen contains as a mean 6.5 grains of phosphoric acid in

the secretion of 24 hours. We know also that a large amount of phosphatic earthy salts is laid up in the body in the osseous and cartilaginous textures, and in mucous tissues and secretions, as well as in smaller quantity in all the solids and fluids of the animal frame. In addition to this, part of the phosphoric acid of the ingesta exists, combined with oleine as oleo-phosphoric acid, and is an important ingredient of nervous matter of the brain and its extensions; whilst another portion is deoxidised, and exists in this nervous tissue combined with carbon, nitrogen, hydrogen, and oxygen, under the form of a phosphorised fat or cere-

bric acid. The excess of phosphates which escape the assimilative powers of the stomach may be traced in the fæces. Berzelius found in three ounces of human excrement six grains of earthy phosphates (Swedish weights.)
To shew you how amply any excess of phosphates in the secretions may be accounted for by their presence in the ingesta, I have calculated the quantity of these earthy salts which exist in an ounce of ten articles of food from the vegetable, and two from the animal kingdom, taking care to choose for the basis of my calculation those analyses which appear to be most trustworthy.

Proportion of Phosphates in articles of Diet.

Article of Food,	Grains of phosphates in an ounce.	Authority.
Potato (<i>Solanum Tuberosum</i>)	23.56	Liebig.
Pease (<i>Pisum Sativum</i>)	9.26	Braconnot.
Maize (<i>Zea Mays</i>)	7.2	Gorham.
French Bean (<i>Phaseolus Vulgaris</i>) . .	4.7	Braconnot.
Wheat (<i>Triticum Hybernum</i>).	4.77	Liebig.
Beans (<i>Vicia Faba</i>)	4.7	Einhoff.
Lentil (<i>Ervum Lens</i>)	2.736	Ditto.
Rice (<i>Oryza Sativa</i>)	1.92	Braconnot.
Milk	1.2	Liebig.
Artichoke (<i>Helianthus Tuberosus</i>) . .	0.96	Payen & Braconnot.
Tuberous Vetchling (<i>Lathyrus Tube- rosus</i>	0.5760	Ditto.
Beef	0.38	Liebig.

From this table you cannot fail to be struck with the enormous quantity of the earthy phosphates which daily enters the stomach with our food; although you must bear in mind that the numbers I have inserted in the tables cannot be taken as absolutely correct; for in most of the analyses I have consulted, the quantities of earthy salts (phosphates, carbonates, sulphates) are placed together, followed by the remark that the salts were "chiefly composed of phosphates," or "nearly all phosphates."
If, for the sake of illustration, we suppose a person makes a hearty meal of bread, meat, and potatoes, we shall find that he is eating a far greater quantity of earthy phosphates than we should have, *à priori*, supposed: thus, if we suppose a meal to consist of
Four ounces of beef 1.52
Do. of wheaten flour made into
bread or pudding 19.08
Three ounces of potatoes 94.24
114.84
it is evident that upwards of 114 grains of earthy salts, consisting chiefly of phosphates, would enter the stomach.
It is obvious that another source of the excretion of phosphate in the urine is to be

found in the destructive or secondary assimilation of nervous matter in which phosphorus enters as a component. This view was propounded and illustrated by Dr. Prout long before Professor Liebig's work appeared, although, in common with the prevailing fashion of the day, and forgetful of the merits of our own illustrious countryman, the disciples and followers of Liebig have given the merit of this idea to him. Most, indeed, of this number appear to have been ignorant that a similar view had been announced by Dr. Prout. As the nervous mass must, in common with other tissues of the body, be daily and hourly undergoing a change, fresh matter being deposited and the old absorbed, during which process its particles undergo a secondary assimilation (Prout), or metamorphosis (Liebig), phosphoric acid is generated, and, combining with bases, escapes in the urine.
The discovery of phosphorus as an element of the mass of the brain is due to Vauquelin; and, according to his analysis, it contains 1.5 per cent. of phosphorus. This statement has been verified by many subsequent observers, especially by M. Couerbe, and more recently by Fremy. According to the latter, the nervous matter consists of

Albumen	7
Fat	5
Water	88
<hr/>	
100	

This cerebral fat is a mixture of olein, margarin, oleic, and margaric acids, with cholesterine, oleo-phosphoric, and cerebrie acids; the latter being wholly or partly combined with soda (*Annalen der Chimie und Physik*. Band, 40). The oleo-phosphoric acid is, by boiling, resolved into oleine and phosphoric acid; the cerebrie acid is composed of

Carbon	66·7
Hydrogen . . .	10·6
Nitrogen . . .	2·3
Oxygen	19·5
Phosphorus . .	0·9
<hr/>	
100·	

In addition to this source of phosphoric acid, we must not overlook the fact of the albuminous tissues containing phosphorus, and hence of their affording, by the process of obstructive assimilation, another supply of this element.

Thus far I have endeavoured to point out

to you the probable source of the phosphates of the urine, more especially of the triple salt. But it is evident that phosphates, especially the calcareous combinations, may be discovered in large quantity in the urine, quite independent of any organic or functional lesion of the kidney. In fact, cases not unfrequently occur in which phosphate of lime in particular, less frequently the magnesian salt, is poured out by the mucous membrane of the bladder, mixed with mucus. All mucous secretions contain the phosphoric acid combined with earthy bases, and hence, if an excess of the latter is secreted with the vesical mucus, it may be washed away by the urine, and form a deposit. This is by no means unfrequent in the irritable bladder depending on the irritation of chronic cystitis, prostatic diseases, &c.: we have a perfect analogy to this in the calculous concretions found in the ducts of glands furnishing mucous secretions. These are all prone to secrete phosphates in too great an excess to be washed away with the secretion; they are, therefore, retained, and form a calculus. These, from whatever part of the body they are obtained, present nearly the same composition.

At our next meeting I shall conclude my remarks on this class of sediments, and pass

to the consideration of those which present evidence of organization.

ON THE
HOMOLOGY OF THE FOETAL
CIRCULATION.

BY THOMAS WILLIAMS, M.B.

Tutor on Healthy and Morbid Microscopic
Anatomy, at Guy's Hospital.

(For the London Medical Gazette.)

It is now a fundamental principle in the science of embryology that the ovum of the mammiferous animal, during the progress of development, exhibits phases of structure which, although transient in duration, present the most remarkable correspondence with types of structure which belong persistently to animals inferior in the scale. It is therefore admitted to be necessary, in order to the attainment of the greatest perfection in the details of organic structure, that nature should first realise the

simplest formative idea, and subsequently make advance along the typical gradations of the extended scale which so remotely separates the most simple from the most complex and perfect of living forms. So that if regarded in the light of a universal and abstract law, language of mathematical exactness and precision might be employed in the enunciation of this developmental principle. If the correctness of this be admitted as a general fact, it may be certainly reduced to the definite proposition that the higher organic form is nothing more than a *multiple* of the lower; the highest only a compound multiple of *all* below it; and conversely, the simplest a remote submultiple of the highest.

When thus contemplated, there is confessedly an imposing air of universality about this principle, which may be apparently received as a trium-

plain proof that physiological science is susceptible of generalisations more extended and comprehensive than any of which the science of inanimate matter is capable. But there are exceptions in the details of its operation, which arise as real objections against the implicit recognition of this law, at all events against its pretensions to universal applicability. It is at present proposed to consider these exceptions with reference only to a few partial particulars.

The analogy is perhaps admissible which physiologists have generally announced between the character of the circulation, as it primitively appears in the vascular lamina of the mammiferous ovum, and the type of the circulating system which obtains as a permanent formation in many of the inferior orders of invertebrate animals. In the succeeding phase the central vessel assumes the higher characters, which distinguish the propulsive apparatus in the circulation of fishes; a simple auricle, and an equally simple ventricle, now constitute the sum of the cardiac centres. A subdivision, or rather a multiplication of the cardiac cavities, subsequently occurs, which exalts the mechanism of the apparatus to the standard of the reptilian type. It must not be supposed that the bulbus arteriosus of fishes, although it composes a third element in the propulsive system, is a true cardiac cavity; or the analogue of the second auricle of the reptilian heart. It is a collateral or superadded provision, made in obvious accordance with the strictest hydraulic principles. The intervention of the branchial capillaries* between the two segments of the circulating system renders necessary the provision of the auxiliary force realised in the aortic bulb. (This is not the occasion on which to shew the physical principles on which this object is accomplished). The same necessities exist in the case of the foetus of the higher animal; the existence, namely, of a *branchial* circulation, and it is accordingly proved that the same provisions are temporarily made. This is not true in detail of structure, but only in *type*. Let all these be admitted as correct correspondences, which in great

probability is a legitimate admission. The process of evolution proceeds. The aortic dilatation contracts, the rudimentary branchiæ disappear, and a second auricle is developed. It is now that the most interesting part of this subject approaches. It is evident that adapting nature has now advanced the organic standard of the new being into an actual parity with the reptilian model; that is, the ventricular segment of the heart consists only of *one* chamber, while the auricular is subdivided into two.

Like the former correlation, this is not exactly true. If the *right* ventricle in the instance of the foetus were supposed altogether absent, the three remaining chambers would more completely resemble the cardiac system of the reptile; the single ventricle would assume at once the branchial (placental, or pulmonic) and systemic characters. It is quite capable of demonstration that the septum *ventriculorum* occupies a period of four weeks in its completion; its formation commences at the 4th and is completed by the 8th week. The development of the *auricular* septum, however, does not begin until the 10th or 11th week; and is completed about the 3d month. Before the development of the ventricular septum, it is implied that the propulsive segment of the heart consists only of *one* cavity. In regard to the interposition between the two chambers of the auricular partition, in consequence of the persistence of the oval foramen, it is at once seen that no alteration of *type* is produced by its ordinary and incomplete formation. Let it now then be determined what are the real terms of the alleged analogy between the stage of foetal evolution, which, indeed, continues throughout the term of utero-gestation, and the form of the circulating system which is proper to and permanent in the reptile. In the crocodilian, the highest, as well as the amphibious, the lowest reptile, the arterial stream which returns from the lungs, and the venous current which reflows from the general system, admingle in the common chamber of the ventricle. In the foetus this admixture happens in the inferior cava; *here* the confluence occurs between the placental and venous streams. The ductus arteriosus in the mammiferous foetus cannot be viewed as the analogue of that freer communication which exists

* Certain remarkable peculiarities in the circulation of fishes, which the author has recently proved, will be discussed in a future number.

between imperfectly divided ventricles of the reptilian heart. In the reptile the blood is exactly the same in every part of the circulating system; with the exception only of that returning from the lungs. In the fœtus, on the contrary, there is an appreciable amount of difference between the cephalic and caudal currents; yet the former, which is the more arterial of the two, possesses only mean qualities, or those precisely intermediate between venous and arterial blood, for the placental and caval streams nearly equal each other in magnitude. In relation, however, to the blood which circulates the posterior extremities, it is at once apparent that in nutrient properties it is inferior to the systemic fluid of the really cold-blooded animal.

From a careful examination of the anatomical character and dependence of the Eustachian valve, notwithstanding the opposing experiments of Dr. John Reid, I have recently convinced myself that it is mechanically inefficient as a means for preserving the individuality of the two caval currents as they traverse the chamber of the right auricle; at the period of its diastole, when the auricle has attained a moderate limit of distension, it may be readily demonstrated that the two streams must freely intermingle. It is not true, therefore, that the difference of quality is so considerable as that generally taught by anatomists between the blood distributed to the anterior segment and that circulating the posterior segment of the body in the fœtus.

It must, then, be admitted that while the detailed mechanism of the cardiac apparatus in the mammalian fœtus is strikingly dissimilar from that which is proper to the reptile, the circulating blood in the two instances is, notwithstanding, assimilated by the most striking affinity of character. But if this similarity of property, and organic character, be fundamentally correct, the reflective inquiries at once suggest themselves—How is it, then, that one is cold-blooded and the other warm-blooded? How is it that the heart of one pulsates with double vigour and frequency, while that of the other struggles out its laborious beats with so much slowness; that the temperature of the one exceeds the limits of the maternal heat, while the other sinks to the standard of the surrounding me-

dium? These inquiries suggest the consideration of several analogous and differential conditions. The temperature in the two instances is certainly determined by that of the surrounding element. The fœtus exhibits exactly the same temperature as the internal surface of the uterine walls, and the liquor amnii. In making other observations upon the pregnant rabbit, I have more than once incidentally proved that the thermometer mounts by several degrees when removed from amid the convolutions of the intestines and planted in the interior of the gravid uterus. The uterine parietes generally are unquestionably the scene of great comparative activity of circulation. The interposed layer of the animal fluid offers a favourable medium for the conveyance of the heat thus rapidly generated towards the exterior of the new being. From recent observations, I am disposed to believe that the temperature of the maternal system is elevated altogether during the period of utero-gestation; but that certainly the temperature of the uterus itself is raised beyond that of the abdominal cavity. So far, then, the correlative conditions in the case of the reptile and the fœtus are closely correspondent. But there are now some discrepant points to be adjusted. Notwithstanding the slowness with which the nutrient process proceeds in the two cases, there are striking differences in the comparative velocities of the two circulations. The fœtal heart performs double the strokes of the maternal organ, and considerably more than double the number of the cardiac pulsations in the reptile. It is evident that the surrounding any more than its own proper heat will not account for this multiple of frequency; for if so, its temperature ought to be double that of the mother, which it is not. There must be some other cause, then, for this remarkably augmented frequency in the cardiac pulsations of the fœtus. It is not apparent that the explanative argument can be derived from the greater excitability of the nervous system. Some physiologists, I believe the idea originated with Dr. Hall, have supposed that this double frequency exactly agrees with the idea that the two ventricles contract at alternate times. The two ventricles are known also, to be supplied by two independent

and separate arterial streams, although there is but one coronary vein. But suppose this hypothesis positively to embrace the truth—that the systole of the two ventricles is performed at regularly alternate periods—it must of course follow that the pulsations of the cephalic and brachial system of arteries should be exactly one-half the frequency of the beats in the abdominal and crural: since the out-going current in the ascending aorta and its dependent branches can obey *only* the action of the left ventricle, while confessedly the descending stream would acknowledge the *two-fold* agency of the two ventricles. But let the correctness of this view be momentarily admitted, and let us inquire into the necessary results. It appears almost certain that if the undulations in the two fluid columns—that, namely, urged by the right side through the pulmonary artery and arterial duct, and that driven by the left side through the aortic arch—or, to express the fact in more precise language, if the phases of elevation and depression in these two conjugating currents be not exactly coincident, it obviously follows that the resultant stream would be continuous and *unpulsating* in its course; and this must be the consequence if it be actually true that the ventricular contractions are alternate, and *not contemporaneous*. So that the eccentric conditions would be realised in the system of the foetus, of a central organ performing 150 pulsations in a minute, the pulmonary artery and ascending aorta and its branches undulating with a frequency of 75 waves in the same period of time, while positively the descending system does not pulsate at all*. This might be readily proved by the obstetrician. But I think it will be admitted that its importance scarcely requires a confutation so grave. It is sufficient to remark in disproof, that the arteries of the funis pulsate synchronously with the foetal heart.

It now becomes plain that the peculiarities of the foetal circulation must be explained on some sounder and more philosophic principles: and it was not until a comparatively recent period that these principles could be either recognised or applied. Since the late observations of Dr. M. Barry,

* I have proved that the abdominal aorta of the fish does not properly *pulsate*.

Gulliver, and Wharton Jones, and the subsequent luminous generalizations of Dr. Carpenter, the conclusion appears well founded that in the blood of the young of all vertebrata the colourless corpuscles preponderate over the red particles, this preponderance being the greater as the foetus is younger. As regards the diminished proportion of the red particles in the foetal blood, the fact coincides well with the views of Mr. Wharton Jones in relation to their functions—that, namely, of maintaining the excitability of the nervous and muscular systems. But it does not appear that the number of the red corpuscles in the foetus is exclusively adequate to the efficient maintenance of its known excitability. Müller has proved by direct observation that the blood of the umbilical vein is scarcely or not at all distinguishable in colour from that of the umbilical arteries, and Dr. Carpenter has instituted a comparison between the contents of the placental vessels and the *chyle*—not the pulmonic blood—of the adult animal. It is believed that in equal volumes of reptilian and foetal blood, a similar proportion of the *coloured* corpuscles would be found; while in regard to the *colourless* globules they would be far more numerous in the latter. Since the time of Hunter, two principles have become axiomatic in physiology: first, that the red particles are directly in proportion as the energies and demands of the muscular and nervous systems: and secondly, as the volume of oxygen consumed. The diminished proportion of these corpuscles in foetal blood conforms with, and confirms, these important principles; the fact likewise affords clear confirmation to the views of Liebig in reference to the functions of the red particles as vehicles simply for the transmission of oxygen from one part of the system to the other; while it opposes with almost equal force the hypothesis of Dr. Carpenter, which assigns to these remarkable bodies in part the office of elaborating the liquor sanguinis into some higher organic principle, or of converting albumen into fibrine.

From the concurrent weight of these observations, it may be received as most probable that the blood circulating in the placenta receives only a very small comparative volume of oxygen, and it is in intimate agreement with this cir-

cumstance to perceive that positively the foetal economy requires but a very inconsiderable proportion of this element. According to the recent inductions of Liebig, the most direct agency of oxygen consists in that of oxidising *away* the effete materials of the structure.

In the foetal organism this process of oxidising disintegration is as obscure as the volume of the consumed oxygen is small. It is unquestionable that the most active organic process in the foetus is that of growth—the constant superposition of nutrient elements—as in old age it is the process of decay. In the former case, therefore, a small supply only of oxygen is required; while in the latter, the disintegration of the fabric being rapid, the consumption of this element must be great. It becomes consequently apparent, that the most important of all conditions to be realised in the foetal organism must be that of supplying the materials of growth. Then, since neither a great volume of oxygen, nor a great proportion of red particles, is necessary to the accomplishment of this object, a copious provision of either would be certainly superfluous. In conclusion, then, there are several facts with reference to the character of the foetal circulation to be accounted for. First, the small amount of red particles, entailing a diminished consumption of oxygen. Secondly, the doubly rapid rate of the circulation. Thirdly, the great preponderance of colourless globules. These are peculiarities which belong exclusively to the uterine foetus of the mammiferous animal.

It is thus shown that there is a want of proportion between the volume of oxygen consumed, the red particles, the amount of the muscular and nervous expenditure, and the rate of the circulation. The generalisations of Hunter, therefore, encounter a striking exception in the laws of the foetal economy. I believe the real explanation of these interesting circumstances to be contained in the following reasons. The rate of growth appears to be determined, first, by the proportion of the colourless corpuscles, or of fibrine in the liquor sanguinis; secondly, by the rapidity of the circulating stream. These two conditions are eminently realised in the foetal system, and the consequence of rapid growth is insured.

As already stated, the quantity of oxygen consumed is small, and the red corpuscles exist only in small proportion, so that neither of these agents can contribute much towards the maintenance of this inordinate rate of circulation. But these conditions would be entirely inoperative in the absence of the proper temperature. In the adult this is immediately dependent upon the mutual agency of atmospheric oxygen and the red particles—the organic process, secondary assimilation; and in the foetus—not by the analogous process of placental respiration—it is in greatest proportion derived from the heat of the medium which it inhabits. It is the comparatively elevated temperature of the uterine parietes and liquor amnii that occasions and maintains the remarkably rapid rate of its circulation.

When the transition is made from the intra-uterine to the atmospheric mode of living, some of these conditions undergo a most complete reversal. This transition is accomplished by the adoption of the most remarkably foresighted precautions against the injurious operation of the altered circumstances into which the new being is thrown. It was while studying the changes which occur in the lungs, when commencing their functions as agents of atmospheric respiration, that these reflections first presented themselves to my mind. At birth, the physiological dangers which immediately affect the child are two-fold. First, if the lungs were to suffer complete and perfect distension by the air at the very first act of inspiration, and the process of atmospheric breathing thus to acquire at once its maximum efficiency, it is unquestionably plain that the few red corpuscles at this period in its blood would be inevitably super-oxidised, and even completely disorganised, just as the voltaic fluid transmitted along a small metallic wire breaks up the arrangement of its component atoms, in consequence of the absence of all relation of equality between the bulk or substance of the wire and the calorific agency of the voltaic current; and so, likewise, in the foetus, the process of growth would be immediately converted into one of rapidly destructive assimilation. These formidable consequences are, however, wonderfully averted by the creation of a mechanical difficulty against the too abrupt and

profuse penetration of the ærating element into the remote parenchyma of the lungs. I have proved, on several occasions, that the few first acts of respiration in puppies, pigs, and also in the child, effect no more than the inflation of a few *vesicles only* in different portions of the organ. In proportion as the process is continued, and as the muscular and nervous systems are developed, the pulmonary structure becomes more uniformly distended, and the area of the breathing surface is correspondingly multiplied. The transition, thus, from a cold-blooded to a warm-blooded character, with respect to the properties of the circulating fluid, is accomplished by steps of the most provident and cautious progression.

By the process of analogical reasoning which I have here attempted to institute and follow out, it certainly appears that a very probable and approximative determination may now be made, in regard to the respiratory value of the placental agency. If it be true that atmospheric breathing commences progressively, the inference must be correctly founded, which argues that the amount of placental æration, as performed for a period of given duration immediately *before* birth, must be very nearly equal to the amount of the process of respiration as accomplished by the lungs within the same period immediately *after* birth; and as it is within the range and power of direct observation to establish that it is mechanically impracticable to introduce any other than a small and gradually increasing volume of oxygen into the blood, through the channel of the collapsed and resisting parenchyma of the unexpanded lungs, at this incipient period of ærial existence, it seems quite legitimate to maintain the associated conclusion that the standard of the placental æration is below the type which is proper even to the inferior reptiles. This inferior measure of oxidation appears likewise satisfactorily to account for the remarkable absence of excreta from the foetal organism; for continued growth, unfettered by the counterpoising forces of decay; for a wisely regulated addition of materials to, without any appreciable subtraction from, the sum of the increasing organism.

INFLUENCE OF THE MOON'S RAYS.

To the Editor of the Medical Gazette.

SIR,

IN your valuable periodical of the 24th of February, I noticed with great pleasure an article by Mr. Thompson, on the supposed influence of the moon's rays as a cause of disease in tropical climates, which so closely agrees with the view I had taken of the subject that I feel inclined to offer a few remarks in support of the same.

During an intertropical voyage, I frequently heard from the seamen of all grades long accounts of the dangers of sleeping on deck in the moon's rays; such as being struck moon-blind, palsy of the face, &c. These accidents, I explained, arose, not from the rays of the moon, but from the quantity of moisture in the atmosphere, which is much greater in strong moonlight nights than otherwise; and, of course, a person sleeping in the open air at such a time would be liable to attacks of the kind.

This I constantly maintained was the only cause, and that the rays of the moon had no more to do with it "than the man in the moon:" but I found no converts to my theory; nobody believed a word about it. Again, it was said that meat exposed to the moon's rays during the night would be found putrefied in the morning, and full of maggots. This I also contradicted and proved to be erroneous by the following conclusive experiment. I hung up at night a piece of fresh mutton exposed to the rays of the moon, and, at the same time, another piece in the shade away from its influence; both these pieces, in the morning, presented exactly the same appearances, rather tainted, but no maggots, and not different from what we would expect to find meat in the tropics, where it will not keep sweet more than four-and-twenty hours.

When sailors see a man asleep on deck in a moonlight night, they invariably throw something over his face to screen it from the moon's rays, and prevent the ill consequences supposed to be caused by them. This it certainly might do, but on a different principle: for by covering the person he would not be so likely to take cold from the dampness of the atmosphere, which is

the real cause of these pretended moon-strokes. However, it is difficult to overcome a prejudice so deeply rooted, not only amongst seamen, but also amongst very intelligent persons, many of whom I have frequently heard maintain the same erroneous opinion: but "*magna est veritas, et prevalebit*," The moon's rays have no more to do with it than the moon was supposed by the ancients to influence the catamenial periods; but as people who have slept exposed to the rays of the moon are frequently found affected in various ways, the conclusion naturally come to by an unscientific observer would be that those diseases were caused by the rays; and I think, therefore, that the clear and rational explanation of such phenomena, given by Mr. Thompson, cannot be too widely diffused and made known, so as to overthrow a very general popular error, which, I believe, has never before been treated and explained in a manner so able and satisfactory.

I am, sir,

Your obedient servant,
J. BERNCASTLE, M.R.C.S. &c.

London, March 13, 1843.

ON PRIMARY CANCEROUS DEGENERATION AND ULCERATION OF THE LUNG.

BY D. MACLACHLAN, M.D.
Physician to the Royal Hospital, Chelsea.
(*For the Medical Gazette.*)

PRIMARY cancer of the lung is, I believe, very generally an obscure affection, and even in secondary cases the disease is frequently latent, remaining altogether unsuspected. This obscurity has arisen, in a great measure, from the want of carefully recorded cases, the occasional absence of local symptoms, neglect of the physical signs, or, where these have been noted, their reference to other sources of common occurrence producing similar signs and symptoms, and, by their frequency, exciting little interest in the observer. A post-mortem examination is then, perhaps, omitted, and the case passes away without the true nature of the disease being discovered.

Until the appearance of Laennec's immortal work on Auscultation, very little was known of malignant diseases

of the lung. They seem to have been regarded as almost, if not always, secondary affections, and in our own country, so late as 1825, Mr. Wardrop, in his edition of Baillie's Works, vol. 2, p. 67-68, says, "melanoid, hæmorrhoid, and scirrhus tubercle, when they attack the lungs, appear only as a secondary form of the disease."

There can be no doubt that *primary* cancer of the lung is rare: very few cases are recorded, and whether primarily or secondarily affecting the lungs, the ulceration of cancerous depositions in this situation is still of less frequent occurrence.

Much as we owe Laennec, it is to subsequent writers that we are chiefly indebted for the information we possess on this subject, and to none is the profession under greater obligations than to Dr. Stokes. The work of this eminent physician, on the Diagnosis and Treatment of the Diseases of the Respiratory Organs, published in 1837, contained all the knowledge we had then acquired of the nature of cancer and fungoid disease of the lung. Since then fresh facts have been collected, and a valuable paper published by Dr. Hughes in Guy's Hospital Reports for 1841, details several interesting cases, while the works of Hodgkin, Walshe, and the instructive lecture by Dr. Taylor, in the Lancet for March 1842, give much additional information.

Dr. Stokes has been carefully investigating the subject since his volume issued from the press, and we have the results of his labours in an interesting memoir which is inserted in the Dublin Journal of Medical Science, for May 1842. Those who are desirous of arriving at "the actual state of our knowledge of the history of thoracic cancer" will consult this memoir, and the work of Dr. Walshe, "On the Physical Diagnosis of the Lungs," with great advantage.

These reflections have been suggested by the occurrence of a case of *primary cancerous degeneration, and ulceration* of the *whole* of the right lung, which has recently been under my care in the infirmary of this establishment, the account of which may be considered a contribution to the history and pathology of intra-thoracic cancer; and, as the case presented some peculiarities, it may probably assist the future observer in forming a diagnosis of what

may very generally be still regarded as an obscure affection.

J. H., æt. 62, was admitted into the infirmary of this hospital, on the 4th of October 1842, complaining of a very frequent dry cough, difficulty of breathing, especially in the recumbent posture, and general debility. For several weeks before admission he had been attending the dispensary attached to the infirmary, with these symptoms, which had been gradually and progressively increasing from their commencement. He had derived no benefit from the means employed, and passed restless nights, in a sitting posture, with a teasing, tickling dry cough, unaccompanied with pain in the chest, or fever. The face was sallow, and, particularly about the eye-lids, occasionally œdematous. The urine was said to be scanty. He came under my observation on the 9th of the month.

Physical signs.—At this period, the 9th of October, the left side of the chest sounded clear on percussion, and the respiratory murmur was puerile, without râles of any description. The right side was dull all over, but not unequivocally so in the mammary region, and the respiratory murmur, feeble throughout, in some places extinct, was accompanied with an occasional muco-crepitating ronchus along the spine.

No impression was made on the symptoms by medicine. He continued to pass almost sleepless nights with the cough, and the difficulty of breathing forced him to sit half erect in bed, the cough and dyspnœa increasing on his assuming any other position. On the 28th of October, I made a careful examination of the chest, having hitherto found it impossible to satisfy myself as to the precise or even probable nature of the case. This examination, though conducted with great exactitude, and with every attention to the symptoms and collateral circumstances, left me almost equally in doubt and uncertainty.

The dulness on percussion had progressively increased. By this time it was perfect, particularly in the posterior regions of the chest, and the walls resisted the fingers. Respiration had entirely ceased in the lung, and though there continued a slight vocal resonance along the base of the right scapula, it was much less marked than on the opposite side; and no vibration

whatever was communicated on applying the hand. The right side appeared to move *en masse*; the upper intercostal spaces remained natural, neither sunken nor prominent; posteriorly and inferiorly they were less marked. Mensuration detected no difference, but, to the eye, the upper part of the right side was contracted in its antero-posterior diameter, while lower down it was fuller, bulging considerably posteriorly. The right hypochondrium projected, and elicited a dull sound, for two or three inches beyond the ribs, on percussion. No enlarged veins were observed on the chest or abdomen; both jugulars were of natural size, probably a little dilated. The heart's action was normal, and unaccompanied with any murmur. No note was taken of the extent of the sounds, or whether more audible on the right than the left side. The pulse at the wrists was regular but feeble. There was no difficulty in swallowing until two or three days at most before death, and the patient's appetite was but little impaired. He had passed less urine lately. The constant teasing dry cough, and the difficulty of breathing, were the only symptoms of which he complained, and he was still free from any pain in the chest.

From the period of this examination no perceptible change took place in the physical signs: the respiration remained extinct, with diminished vocal resonance; total absence of vibratory sensation on applying the hand to the right side, and universal dulness on percussion; while, on the opposite side, the respiration was puerile, and the resonance natural. The cough, hitherto dry, was at length occasionally accompanied with a scanty brownish mucous expectoration. At no period was there hæmoptysis. On the 7th of November, he, for the first time, complained of uneasiness, scarcely amounting to pain, in the right side of the chest. His face was now generally swollen, especially in the morning, and the conjunctivæ were congested. About this time his wrists and hands became œdematous, and by the 16th the œdema had extended up the arms to the shoulders. The œdema advanced rapidly, extended over the chest, but never affected the lower extremities. He was now wholly confined to bed. On the 18th, his countenance was fearfully

altered; the eyes, congested, projected from their sockets; and both arms, enormously swollen, equalled the thighs in circumference. The dyspnoea and cough had increased in proportion. The poor man sat doubled up in bed, his chest resting on his knees, or, turned over on the right side, he sought in vain for relief to his breathing, supporting himself, in this position, with his face on the pillow. His intellects remained clear. At length, exhausted by his suffering, he suddenly expired on the morning of the 22d November, probably about three months from the commencement of the disease.

Anatomical appearances thirty hours after death.

The whole of the right side of the chest was filled with a firm unyielding mass, pushing the liver two or three inches below the margins of the ribs, and adhering so strongly to all the neighbouring structures that it was found impossible to detach it without a tedious dissection, and the attempt to remove the whole lung was abandoned. That portion exposed on raising the sternum presented a rose tint. Cut into at any part, the knife penetrated innumerable excavations, varying in size from a pea to a walnut. These cavities, universally disseminated throughout the lung, were, for the most part, filled with a thick, yellow, foetid, diffuent pus; others contained thin sanious offensive matters, while a third set, and these were fewest in number, were occupied with a whitish pul-taceous substance, resembling softened brain. The walls of these various cavities were ragged, broken down, and not lined with any membrane. At the root of the lung, encroaching on the heart, and adhering firmly to the pericardium, there was a large, dense, white, knotty substance, surrounding the vena cava superior, compressing it and the right bronchus, and almost obliterating the right branch of the pulmonary artery. This firm tumor resisted the knife, and the incised surface, of a white colour, presented a fibrous texture resembling true scirrhus. From the cut surfaces there exuded, on pressure, a creamy fluid appearing in drops at various points. Immediately contiguous to this scirrhus mass, the abscesses observed in other portions of the lung were here of diminished size;

the nearer the surface, the larger these appeared to be; and where the lugs could be traced it was of a deep green colour. Several enlarged bronchial glands, filled with black carbonaceous matter, adhered firmly to the tumor, and two or three melanotic tubercles were immediately adjacent.

The left side of the chest contained a large quantity of clear serum. The lung itself was perfectly healthy, cre-pitating, free from adhesions, and the pleura was without any trace of inflammation.

Nothing particular was observed in the heart. The right ventricle was probably a little dilated. As above stated, the right branch of the pulmonary artery was greatly compressed, and nearly flattened.

The liver projected several inches below the ribs, was pale, but, together with the remaining viscera of the abdomen, appeared sound. Excepting in the right lung nothing like cancer existed in any other part of the body; and all the organs but the brain were minutely examined.

REMARKS.—It is not my intention to occupy the reader's time with a lengthened analysis of this important case. The main objects I have had in view are to record the facts relating to the symptoms and physical signs, as far as they were observed, and the morbid alterations exhibited on post-mortem examination.

Until far advanced, the case was exceedingly intricate: I had, besides, laboured under the disadvantage of never having seen a case of primary cancer of the lung, where it was settled beyond dispute by subsequent examination. Various opinions were formed, and I never could satisfy myself of their correctness; nor were others able to determine the precise cause of the various phenomena. There were no external tumors, no enlarged or varicose veins on the chest or abdomen; there was no hæmoptysis, and several signs and symptoms of malignant degeneration of the lung were absent. The disease had evidently made considerable progress before the man came under hospital treatment; and on admission it was obvious that the greater portion of the lung was condensed. Extinct here and there, and feeble throughout, the respiratory murmur

was accompanied, at the root of the lung, with a muco-crepitating ronchus; and the almost universal dulness on percussion, with the incessant dry cough, led to the opinion that this consolidation proceeded either from tubercles or chronic pneumonia. The rarity of the latter, and the frequency of the former, inclined me to the belief that the case was one of a class sometimes met with, in which, for a long time, only one lung is the seat of crude tubercles. The physical signs, however, together with the general symptoms and history, were, as regards either of these affections, incomplete, and gave other indications. At a more advanced stage the case was almost equally obscure. The total extinction of the respiratory murmur in the lung, the unequivocal and universal dulness, the absence of vibratory fremitus, the descent of the diaphragm and consequent displacement of the liver, the detrusion of the side, and the increasing œdema, all indicated effusion into the chest. There was, however, no obliteration of the upper intercostal spaces, such as would likely have existed had there been effusion sufficient to push down the diaphragm and dilate the chest. The œdema was limited to the face, chest, and upper extremities, and there was still some vocal resonance along the base of the right scapula—a sign, however, comparatively, of less value. The general symptoms were not more decisive than those afforded by auscultation and percussion. There was little or no pain in the chest; the patient never complained of any until pointedly asked the question, and then not until the lung had acquired increased bulk, and pressed in every direction. The cough, almost dry, throughout the progress of the case, and the difficulty of breathing, might have arisen from many causes: in themselves they were little to be depended upon; but, in connection with other phenomena, they yielded negative information. The difficulty of swallowing did not occur till a few days before dissolution; but, as the œdema was confined to the upper extremities, it appeared more than probable that this symptom proceeded from interrupted circulation, and that the seat of the obstruction was somewhere about the superior vena cava. No stethoscopic signs of disease of the heart existed, and

in what this obstruction consisted was questionable. That it arose from cancerous disease of the lung was not improbable, though this opinion was merely conjectural, and formed negatively on a review of the case, and on excluding other diseases with which it was earlier confounded.

The rapid progress of the case is worthy of observation. Although, on presentation, the lung appeared to be extensively consolidated, in about a fortnight afterwards there was perfect and universal dulness on percussion, and all respiration had ceased to be heard. It is very probable that the original seat of the disease was at the root of the lung, that the main bronchial tubes had very soon become obliterated; and this, together with the compression of the right bronchus, accounts for the absence of blowing and cavernous respiration, cavernous gurgling, as well as the total extinction of the vibratory fremitus. The absence of these phenomena is an important feature of the case.

The effusion into the left cavity of the chest was very recent. A physical examination was not made for some days before the death of the patient. As to the treatment, it is needless to state that all means were quite unavailing. Sleep was sometimes procured by opiates. Ether seemed to aggravate the dyspnoea. A drastic purgative had, on one or two occasions, a surprising effect in diminishing the œdema; but the cough and difficulty of breathing were hardly ever alleviated.

MEDICAL GAZETTE.

Friday, March 31, 1843.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

COMBINATION.

WHOEVER pays much attention to passing events, must have noticed the remarkable tendency to combination, for different purposes, which prevails on all sides at the present day, and so extensively as to be a leading and

characteristic feature of our time. Our own countrymen, whose mental and bodily vigour has enabled them to recognise the value, and labour for the adoption, of whatever can be applied to good purposes, seem to have bestowed more attention on this new element, and made larger use of it, than any nation in the world.

To those who live in London, the number of associations for the promotion of every thing good, and the suppression of every thing evil, has an appearance rather ludicrous than otherwise. The eye is fatigued, and the heart hardened, by the placarding system so profusely adopted by well-intentioned committees. Our city is like a vast fair, where so many dramas are being acted at the same time, that the *bills* we read lose all attraction.

To see the effects of combination where they are most evident, we should watch them in a village, in the small branches of large associations. If possible, we should have no personal interest or acquaintance with the places or the people. The process is, then, about as instructive and certainly as fanciful as zootomy; or, as the objects are small, though the actions are intense, it is zoomicroscopic, showing an exaggeration like that of a frog's foot under natural and unnatural stimuli. It is not that persons of conflicting interests all hate each other with a more perfect hatred in villages than in cities, but they are brought into more immediate opposition. Mr. A. cannot gain, or lose a patient, without directly affecting the interests of Mr. B. of that ilk. The large vessels of the body lie side by side in great comfort, though working in different directions; if one presses for a time on the other, a good deal of disturbance takes place certainly, but if a chill or a heat, a stagnation, or an *error loci*, take place in the capillaries, the mischief is organic as far as it goes,

and takes longer to repair too; for a dyspepsy or a plethora disperses more quickly than a *nævus* or even a pimple.

Voluntary combination cannot exist without more or less equality among the members; their need of each other's support, by labour or capital, by patronage or sufferage, must be real and reciprocal; this is a simple fact; the mere act of combining is often held to be a proof of equality—this is a mistake. The combination which seems to shew the least of equality, viz. between the great and small, rich and poor, employer and employed; in fact, one of the strongest of all; for their wants and dependence are mutual; so are their will and power to supply those wants. Equality is often assumed, or taken for granted, for the mere purpose of effecting combination where it does not really exist, and this of course is a fiction; but the fact, the mistake, and the fiction, exist together in nearly all voluntary combinations; the first, which is the real element of strength, will be found to depend on the combination being one of real unity, and not of uniformity—unity of interest and of purpose, and consequently of plan and of method. The plan and method, indeed, may differ almost entirely, if real unity of interest and purpose exist. The cohesive force will be sufficient to sustain severe pressure, and to do much work. But the mere uniformity of plan and method cannot bear severe pressure, nor do any work at all. It may present a fair surface, and a broad one, but not a solid nor a strong one. Combinations for purely charitable purposes, or for mutual assurance, can only be strong, permanent, and effective, in proportion as the unity of design and interest is carried out; and if this be really effected, the methods are comparatively unimportant. A hospital or an assurance-office, so defective in principle, or so ill worked, as not to afford relief to sickness, nor security to property,

would fall to pieces though not a harsh word were ever heard among the managers. But hospitals and companies do flourish whose board-rooms sorely try the tempers of their managers and governors, so long as there be no *malap Praxis* in the wards, or errors in the calculations. But an inefficient medical officer, or a defect in the interest table, will do more harm than half a score of irritable governors.

When earnest men are seen clinging with bigoted tenacity to a particular method of reform or conservancy, making the adoption of a single term the test of approval and fellowship, it may be suspected, if not asserted, that there is more of uniformity than of unity in the combination for which they strive.

There are two principal causes which induce men to unite into brotherhood, or societies for effecting specific objects. One is, the sense of an evil to be removed, a weight to be lifted from themselves, which is too heavy for their private exertions; the other is a strong impulse originating from vivid impressions on the mind of a single individual, and thence communicated to numbers; but, however humiliating it may appear, most of the great social efforts which have agitated the world are traceable to what may well be termed despair or enthusiasm. To have effected what they did effect, these movements must have been produced, and the resulting systems sustained by materials of the firmest texture, and when decay has overtaken them, their solidity can be inferred from the ruins which they have left. No human fabric, material or social, is proof against time and force; there is grandeur in the fall as in the elevation of what is really gigantic, but mere aggregations of material, however bulky, of parts however numerous, can excite no other feeling than contempt when wanting in

grandeur of design and solidity of material.

How very few of the associations which have been lately formed have possessed these essential characters—how many are unknown for any useful purposes beyond the precincts of the committee-room. It really seems as if the soundness and efficiency of the whole were inversely as the bustle and tumult at the centre: a really working association is tranquil and dignified at the seat of government, lively and energetic in its distant parts, every member living, feeling, acting, not by convulsive throbs of the centre organ, audible to the by-standers, but by the steady unnoticed current of vigorous health.

It is curious how much of righteous self-discipline, of sound wisdom, is required before men can act together in large numbers with energy and effect. That many fail is most true and lamentable, but that very many are making praiseworthy efforts is matter of sincere rejoicing. It is no small attainment in self-government for a man to sit out a debate of two hours without yielding to the conviction that what he has to say on the subject is better worth hearing than the discourse of his neighbour; the act of speaking one at a time is not attained without labour, nor practised without difficulty. It is a very great attainment to be silent, to go on patiently storing up facts which others may use more than ourselves—to be establishing premises that others may draw inferences, to hand water from the well of truth, that others may quench the flames of error. There are some very well-meaning persons who honestly advocate the extinction of quackery and medical heresy, and other flagrant evils, by act of parliament, and until the authorized brigade shall arrive with its well-appointed engines each man runs hither and thither to dash his bucket of indignation on the

flames he would extinguish; much smoke and hissing are thereby produced, and no little confusion, the well-meaning neighbours getting sadly in each other's way; but what is worse, they forget that

———"Water thrown on fire
By sprinkling does but raise it higher."

So, too, the counter-practice of the druggist, fanned and fed by the prescriptions of the physician, threatens to consume and scorch up the general practitioner. Shall we, then, establish a quarantine to ward off the sick from their abodes, and draw a *cordon sanitaire* round each unqualified blue light? shall we hold meetings, and appoint committees of licensed men who have no practice, to watch and report the proceedings of those who have too much? We think not. We would rather say, convert your day-books into records of symptoms; your ledgers into case-books; and your long bills for draughts and powders into commentaries on the bills of mortality; and the enlightened chymist will be your professional ally; the mere retailer of patent medicines, sweetmeats, and cigars, will no longer be confounded with yourselves—he will have his own gains, but not yours.

VACCINE REPORT.

*To the Right Hon. the Secretary of State
for the Home Department.*

IN making another annual report of the progress of vaccination, we are happy to be able to state that a farther experience of that great resource has confirmed our confidence in it.

Wherever vaccination has been practised carefully, and with those precautions which experience has pointed out as necessary, it has been followed almost universally with success. But we lament it, as one of the proofs of the general reliance of medical practitioners in its efficacy as a preservative, that it has been deferred too frequently until the seeds of small-pox have been re-

ceived into the system and about to produce their natural consequences.

This Board has manifested the propriety of its establishment and maintenance by having never failed to produce efficacious vaccine lymph when called for. This is universally acknowledged to have been a resource in the most urgent circumstances.

HENRY HALFORD—President of the Board.

ARTHUR WHITE—President of the College of Physicians.

HENRY HOLLAND—Senior Censor.

CLEMENT HUE—Registrar.

March 13, 1843.

NOTE IN REPLY TO

DR. GRIFFITH'S REMARKS ON THE BLOOD AND FIBRE.

BY MARTIN BARRY, M.D. F.R.SS.L. & E.

DR. MARTIN BARRY presents his respects to the Editor of the MEDICAL GAZETTE, and requests that he will have the kindness to insert the inclosed, from the Lancet, in reply to the remarks of Dr. Griffith, reprinted in last week's number of the MEDICAL GAZETTE from the Annals and Magazine of Natural History.

London, 27 iii. mo. (March), 1843.

I have to acknowledge the courtesy shown in the remarks of Dr. Griffith, and regret that his opinions differ so widely from my own; but am compelled to say I find nothing in his communication that alters in any particular my views, or that requires more than *general* notice at my hands.

"The appearances observed by Dr. Barry in the blood," which Dr. Griffith thinks were "misinterpreted," I cannot suppose that Dr. Griffith ever *saw*; if I may judge from the description he has given. That they are, however, visible, is proved by the following description given by another, who did see the appearances in question. Whether they have been "misinterpreted" the future may determine.

"Bristol, Aug. 19, 1842.

"Dr. Barry has pointed out to me, among the corpuscles of newt's blood preserved in their own serum, without any re-agent having been applied to them, many which had the form of a flask with a projecting neck, or which might be still better compared to the body of a pair of bellows, with its projecting nozzle. The projecting portion appeared to be a filament, having a much higher refracting power than the general substance of the corpuscle. He also showed me, in a portion of blood to

which corrosive sublimate had been added, a corpuscle which was evidently destitute of the ordinary nucleus, and which contained what appeared to be a filament, which presented transverse markings that resembled those of muscular fibrillæ, the interspaces being oblique. The appearance resembled that of Dr. Barry's Fig. 9 β (Phil. Trans., 1842, plate v.), except that there was no trace of nucleus.

(Signed) "W. B. CARPENTER."

My preparations of muscle have been seen by many, to whom I could refer for their opinions regarding them. Among our own countrymen may be mentioned Robert Brown, D.C.L., and Professors Owen and Sharpey, besides the gentlemen from whom I have received the testimonials at foot. To the kindness of Professor Sharpey I am indebted for the beautiful preparation of muscle from the tail of the tadpole mentioned by Dr. Griffith. The following note was sent me by one who had closely examined that preparation:—

"6, Holles Street, Cavendish Sq.
"Oct. 13, 1842.

"My dear sir,—On returning home to-day, after seeing your exquisite preparations of muscular tissue, I was anxious to express my thanks for your kindness and patience in exhibiting the series to me. I went to your house by no means prepared to admit the existence of the spiral fibre; on the contrary, somewhat prepossessed against such a theory; for while I had already made up my mind as to the non-existence of the discs advocated in Mr. Bowman's very ingenious paper in the Philosophical Transactions, I had not been able to bring my belief to the idea of substituting a spiral thread or fibre to account for the peculiar markings on the muscular fasciculi. You have, however, convinced me, for in several instances I was enabled to follow the spiral thread *round* its axis, and to see the continuity of *both* sides of the chain. In one or two instances I observed it drawn out or separated so far as not to leave a doubt of its reality. In the same way I distinctly recognised the double spiral (especially in one preparation, where the two spirals had not an equal oblique), and I can conceive that the longitudinal lines or fibrillated appearance of the larger fasciculi depends upon the even juxta-position of many minute spirals.

"The reason, probably, I had failed in previously making out this structure resulted from my expectation of seeing this appearance throughout the whole length of a filament; but I now observe how minute is the care necessary to separate parts, and how small often is the portion favourably situated or sufficiently isolated to admit of a distinct view of this curious structure. There are,

also, many circumstances connected with the different refrangibility of objects, of great importance in explaining why a spiral fibre should be so much more easily seen in one tissue than another; and thus it is that reagents are often most usefully applied where different parts of the same object refract the light nearly equally. I *think*, through your help, I have at last settled my belief as to the true character of the markings of muscle, and for which I beg you to accept the thanks of your's faithfully,

(Signed) "JOHN DALRYMPLE."

"To Martin Barry, M.D."

The following, connected with the same subject, was received from Dr. Carpenter, bearing the same date as his testimonial above given:—

"I have this day had the opportunity, through Dr. Barry's kindness, of examining several of his preparations of muscular fibre, especially those from the heart of the turtle and from the shrimp. I have *distinctly seen* single spiral threads continuous with fasciculi; in one or two instances so little elongated as to resemble a corkscrew, in others drawn out more or less straightly. In several fibrillæ, which had been isolated without disturbance of their structure, I have seen appearances closely corresponding with those represented by Dr. Barry in figs. 52 and 56 of his last paper (Phil. Trans., 1842). I may add, that I have seen these appearances even more distinctly under my own microscope, which is furnished with one of Powell's *latest* 1-16th objectives, than under Dr. Barry's instrument, in which lower powers were used.

(Signed) "WILLIAM B. CARPENTER."

The microscope I use is one of Schiek's achromatics, similar to those employed by Professors Ehrenberg, Schwann, and R. Wagner. On this subject I cannot refer to a higher authority than that of Joseph Jackson Lister, who, after a close examination, describes my deeper object-glasses as "very finely corrected every way."

MEDICAL MEETING IN SURREY.

On Friday the 24th instant, March, 1843, the General Practitioners of the County of Surrey assembled at the Coffee House at Epsom, to consider whether any steps should be taken, relative to measures in contemplation, to regulate the general medical profession.

There were present, practitioners of Epsom, Ewell, Chertsey, Weybridge, Guildford, Godalming, Dorking, Leatherhead, Reigate, Croydon, Carshalton, and other places: Mr. Martin, of Reigate, in the chair.

Whereupon, after mature deliberation, it was proposed by Wallace, of Carshalton, and seconded by Mr. Fletcher, of Croydon, and resolved unanimously,

That under present circumstances it is advisable, *without delay*, to petition both Houses of Parliament on the contemplated legislation respecting the medical profession, and that the following petition to the House of Commons be adopted:—

To the Honourable the Commons of the United Kingdom of Great Britain and Ireland, in Parliament assembled.

The humble Petition of the undersigned, Practitioners of Medicine, Surgery, and Midwifery, or, as they are usually denominated, "General Practitioners of Medicine," residing in the County of Surrey,

Sheweth,

That your Petitioners, assuming that the great body of the General Practitioners are the advisers, in ordinary, of by far the largest portion of the population of the country, it is of essential importance that they should be thoroughly qualified as skilful and able advisers.

And, understanding that measures are in contemplation for reforming and regulating the profession generally, are well assured that no reform can be effectual, or permanent, unless, while it provides for the qualifications, efficiency, and respectability of the profession, it shall also be adapted to the wants of the public, as demonstrated by the universal practice of appealing in all ordinary cases to the skill and care of the General Practitioner.

That the supply of an adequately qualified class of General Practitioners is of national importance, must be felt by every observing and reflecting person; and that a legislative re-organization of the profession, your humble Petitioners conceive to be of indispensable necessity, from several causes; and among others, from the various and incongruous modes by which Medical Practitioners procure admission into the profession; there being no less than sixteen different sources, from which certificates may be obtained.

Your Petitioners therefore pray, that on this as well as on other grounds of incongruity and inconsistency in the polity of the Profession, your Honourable House would cause inquiry to be made into the present state of the Medical Profession, and more especially in reference to that of the General Practitioners, in number *ten or twelve thousand*, or perhaps more; delaying any legislative measure, which might lead to the granting of new Charters to the Colleges of Physicians and Surgeons, until the whole subject of medical regulation and reform has been well and thoroughly investigated by a

Committee of your Honourable House, and has undergone adequate discussion in Parliament.

Proposed by Mr. Fletcher, seconded by Mr. J. Wallace, and resolved unanimously,

That one of the Surrey Members be respectfully requested to present the Petition to the House of Commons; and that the other Members for Eastern and Western Surrey be also requested to favour the Petitioners with their support on the occasion.

Proposed by Mr. Bottomley, seconded by Mr. Nash, and resolved unanimously,

That his Grace the Duke of Richmond be respectfully requested to present the Petition to the House of Peers.

Proposed by Mr. Chaldecott, seconded by Mr. Harcourt, and resolved unanimously,

That a Committee be appointed to observe the proceedings of Parliament and the Government on the subject of medical legislation, to consist of nine Practitioners, with power to add to their number, and to call other General Meetings if they should deem it expedient so to do.

Proposed by Mr. Eager of Ripley, seconded by Mr. Hart, and resolved unanimously,

That members of the Medical Profession be recommended to endeavour to call the attention of Members of both Houses of Parliament to the subject of the legislative regulation of the profession—on the importance of the general practitioners to the health and welfare of the community—and on their present position.

Proposed by Mr. Shelley, seconded by Mr. Bottomley, and resolved unanimously,

That the best thanks of the present meeting are due to Sir James Clark, Bart., for his judicious and able Tracts on the education of Medical Men, and on Medical Polity, in the form of two letters, addressed to the Right Hon. Sir James Graham, Bart., her Majesty's Secretary of State for the Home Department; and this meeting recommends those letters to the careful perusal of every Medical Man in the kingdom. Also, that a copy of this resolution be sent to Sir James Clark. Adjourned.

ALBERT NAPPER, of Guildford, Sec.

REDUCTION OF A PROLAPSUS UTERI

AFTER SIXTEEN YEARS' CONTINUANCE.

M. DURANT records an interesting case of this in the Transactions of the Medical Society of Ghent. The wound protruding beyond the external parts, and covered by the inverted vagina, presented a globular tumor, round and contracted at its origin into the form of a circular appendix. The os uteri was clear at its inferior part. The

tumor at its middle part was fifteen and a half inches in circumference. Its external surface was brownish red, and covered with crusts and ulcerations. The long continuance of the affection had seriously injured the general health of the patient—she was pale and emaciated, and subject to sleeplessness, and cramps of the stomach.

M. Durant, before attempting reduction, kept the patient on light diet, and at rest in bed in a proper position ; at the same time dressing the tumor with opiated emollient fomentations. Its surface speedily softened, and the crusts fell off, leaving superficial sores. After six days of this treatment, the operation was performed. It having been ascertained that the rectum and bladder were empty, the patient was placed in the position most advantageous for the entrance of the womb. M. D. then introduced the right forefinger into the os uteri, and burying it, pushed upwards in the axis of the tumor, which itself was placed in the axis of the true pelvis—then retaining the uterus in its place with the left hand, withdrew the finger, and, repeating this manipulation with gentleness, just as one turns the finger of a glove outside in, accomplished the reduction in less than half an hour. He then inserted into the vagina a sponge, cut into the form of a cylinder, and saturated with an emollient decoction, the thick end being highest up, and a cord attached to the other, for the purpose of removing it at pleasure. This sponge-pessary was retained in its place by means of compresses, and the T bandage. The patient did well, speedily gaining flesh and strength. During the after-treatment, which continued for about six weeks, emollient and astringent lotions were employed, and an ordinary-sized caoutchouc ring-shaped pessary was used, the saturated sponge and the injections being passed through its centre.—*Journ. de Méd. et de Chirurg. Prat.*

MEDICAL&CHIRURGICALSOCIETY.

To the Editor of the Medical Gazette.
SIR,
IN the history of almost all societics, whether formed for the cultivation and extension of science or for other purposes, it may be observed that *pari passu* with the prosperity of such institutions, advances a tendency to jobbing and favoritism in their management. The Royal Medical and Chirurgical Society, I am afraid, is about to add another example to the already long list of mismanagements. Not to take up your time with other examples, let me notice that, although the Royal Medical and Chirurgical Society purports to admit as fellows, medical men of all classes, whether physicians, surgeons, or Apothecaries, there appears in the list of

council, the name of but *one* surgeon practising generally.
Now, I am not aware of any cause for such departure from the originally intended tripartite character of the society, except, as I before stated, rank favoritism and jobbing. Again, in the list of vice-presidents is to be found the name of a member elected only in 1840, in whose favour many older and equally worthy members have been passed over and neglected.—I am, sir,
Your obedient servant,
JUSTITIA.

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE XXII.

On protracted and difficult labours.

THE second class of labours includes all those cases in which the head of the child presents, and the delivery is not completed in twenty-four hours. It might be objected to this definition, that there are some cases in which it becomes necessary to deliver artificially before the expiration of twenty-four hours from the commencement of labour; and that there are many others in which the process is protracted ten, fifteen, or even twenty hours beyond this period, without any unfavourable symptom occurring, and where the delivery is at last safely accomplished by the natural efforts. I think, however, with Dr. Denman, that this definition will, on the whole, be found to apply to practice in an advantageous and unexceptionable manner, and that it, in particular, affords a remedy against impatience, and is calculated to guard the practitioner in some measure from premature attempts to give assistance, without incurring the danger of those evils which might be apprehended from too long delay. When regular pains have continued twenty-four hours, the patient and her friends naturally feel anxious to know the cause of the protraction, and whether there are any unfavourable symptoms present to excite alarm. When a labour has continued twenty-four hours, and there is a probability that it will not be completed for some time longer, it is a good rule, whether

you are urged or not by the fears and anxieties of others, carefully to examine the condition of the patient—all the symptoms, local and constitutional—to ascertain, if possible, the cause of the delay—closely and calmly to watch the progress of the case, and promptly to employ the appropriate treatment. Beyond a certain period, it is proved by the experience of all practitioners that a woman cannot continue in labour, whatever the cause of the difficulty may be, without certain hazard, and that the danger is, in most cases, proportioned to the duration of the labour. In the course of 57 years, 78,001 women were delivered in the Dublin Lying-in Hospital, of whom one out of every 92 died, and one child out of every 18 was still-born. In women who were in labour with their first children from 30 to 40 hours, one in 34 died, and one child in five was still-born. When labour was protracted from 40 to 50 hours, one in 13 died. If labour were protracted other ten hours, 1-11th of the women died, and when it went on between 60 and 70 hours, 1-8th died, and nearly one-half of the children. It follows from these statements made by Dr. Burns, from the Tables of the Dublin Lying-in Hospital, calculated by Dr. Breen, that when labour is protracted beyond 30 hours, one woman in 34 dies; in other 10 hours, the danger is more than doubled, for one in 13 dies; then one in 11, and next one in 8. A single case of difficult and tedious labour in private practice, where you are left to your own resources, and where you know not how to proceed, or decide erroneously, will probably, however, have more influence in impressing upon your minds the vital importance of this subject than any general statements which I can make.

Protracted and difficult labours can generally be referred to one or several of the following causes:—

1. Feeble, irregular, or partial uterine action, from passions of the mind, original or accidental debility in the mother, and

other constitutional causes which impair the energy of the brain and nervous system of the uterus.

2. A rigid, undilatable condition of the os uteri, vagina, and other soft parts.

3. Rigidity of the fetal membranes; their premature rupture; imperfect discharge of the liquor amnii; over-distension of the uterus by dropsy of the amnion, and a plurality of children.

4. Shortness of the umbilical cord, from being twisted once or several times around the neck and trunk of the child.

5. Unusual size and ossification of the head of the child; hydrocephalus; the forehead situated under the arch of the pubes; presentation of the face; one of the arms with the head; death of the child, and the distension of its abdomen with air or fluid.

6. Distortion and bony tumors of the pelvis.

7. Diseases of the uterine organs: as cancer of the os uteri; cicatrices of the vagina, and cohesion of the labia; ovarian and uterine tumors within the pelvis.

1. Of protracted and difficult labours, from feeble, irregular, or partial uterine action.

The uterine contractions may be of short duration, continuing only for a few seconds, or they may return only after long and irregular intervals, so that many hours may elapse before the first stage of labour is considerably advanced, though the orifice of the uterus be soft and dilatable. This does not usually depend on constitutional debility, for in many women exhausted by tubercles of the lungs and hectic fever, the uterus contracts forcibly and regularly in all the different stages of labour, and I do not recollect being obliged to apply the forceps in a single case of this description. Some women are liable to have one labour protracted from this cause without any assignable reason, and all their succeeding labours are speedily accomplished. Others have this slow imperfect action of the uterus in all their labours, and it appears to depend on a sluggish, dull, torpid, inactive condition both of body and mind; in a word, on a want of proper nervous irritability in the constitution. In some women, from observing the progress of former labours, we can almost predict with certainty that in all succeeding labours the first stage at least will go on very slowly, and occupy a considerable number of hours, though there be no rigidity of the os uteri or membranes, or over-distension of the uterus, and the umbilical cord does not surround the neck of the child. "The circumstances attending labours," observes Dr. Denman, "are generally alike, yet in many women they are

marked with some peculiarity, most frequently in the time required for their completion. When there has been an opportunity of observing the progress of labour in two or three instances, we shall be able to tell what will be the probable termination of a future labour in the same person, and when it will take place; and we can no more control the order of a labour in one woman, so as to make it correspond with, or exactly resemble, that of another, than we can judge of the quantity of food which one person may require by that which is sufficient for another, or regulate any other function of the body. One woman may require twelve hours for the production of the same effects in the time of labour that another may finish in four hours: and it would be in vain to attempt to make an alteration, because the reason exists in some essential property of the constitution, beyond the power of medicine, or of any other method, to alter." You will readily perceive, from this statement, how unnatural the rule must be which some distinguished accoucheurs have laid down for the treatment of all cases of labour, viz., that the first stage should invariably be completed in twelve hours from the commencement of regular pains, and how impossible it is to act upon this principle without producing the greatest mischief.

Sudden and violent emotions of the mind have a powerful influence over the contractions of the uterus, and may at once completely suspend them, or greatly impair their energy. Dr. Merriman relates the case of a woman who was seized with a fit, from which she never recovered, in consequence of a medical practitioner being abruptly introduced into her room to whom she had previously taken a violent dislike. I saw, in consultation with Mr. Jones, Soho Square, a young married lady in labour with her first child, not long since, in whom the uterine action was almost completely suspended, and an attack of puerperal convulsions threatened, from an excessive fear of dying during delivery, or being subjected to some frightful operation. A female friend had put into the hands of this lady, when seven months pregnant, the *London Practice of Midwifery*, and she could read no other book during the latter months. The consequence was, when labour commenced, she thought of nothing but flooding, convulsions, arrest and impaction of the head, deformed pelvis, and all the operations so minutely described in that work. The uterine action was so completely destroyed by terror, that she would have sunk in a few hours had the delivery not been effected by artificial means. "Such extreme cases as this rarely occur," says Dr. Merriman; "but various kinds of mental excitements continually prevail, and, without producing the more violent ill consequences,

tend, however, to disturb and interrupt the favourable process of child-birth. The influence of mental emotions over the act of parturition was strongly and very extensively exemplified not long since on the occasion of the sudden decease, immediately after delivery, of an illustrious and most amiable personage. Indeed, this calamitous event is still found to operate unfavourably on the minds of patients in a certain rank of life."

In protracted labours, arising solely from feeble and irregular uterine action, if the pulse is not much accelerated, the surface cool, little thirst, tongue moist, no tenderness of the abdomen, no unusual sensibility of the vagina and os uteri, and the dilatation is advancing, however slowly, we ought not to interfere. Many hours often elapse before the first stage of labour is completed, yet no bad effects from the pressure of the head of the child upon the soft parts, or exhaustion or fever, will be produced, if the apartment is preserved cool, if all voluntary efforts to bear down are checked, if the posture is occasionally changed, and if nothing but mild nourishment and diluents be allowed. If there is thirst and slight pyrexia, some purgative, as castor-oil, which operates quickly, should be given, or a stimulating enema exhibited. Purgatives and clysters often have the effect of exciting uterine contractions, and they assist in preventing fever and inflammation from being excited in the progress of a tedious labour.

If opiates are ever administered with success in these cases, it can only be at the commencement of the first stage of labour, before the membranes are ruptured, with the view of entirely suspending for a time the uterine contractions, and procuring rest. When the os uteri is fully dilated, and the membranes ruptured, I have never seen opium given with advantage, and I have repeatedly seen it produce bad effects. If the first stage of labour without rigidity of the os uteri is greatly protracted, it is often of advantage to rupture the membranes before it is fully dilated, to raise the head that the liquor amnii may entirely escape, and to make gentle pressure with the finger around the margin of the os uteri during the pains, or to press up the anterior lip where it remains down between the head or symphysis pubis, and when the posterior lip has disappeared. Even in first labours, before the os uteri has been fully dilated, where there has been danger of exhaustion, I have adopted this practice in some cases with the most decided advantage. You will not, however, infer from this, that I wish you to suppose that it is justifiable, in ordinary cases of labour, artificially to rupture the membranes.

It is chiefly in cases of protracted labour from deficient uterine action, that ergot of

rye has lately been so strongly recommended and so generally employed. From the days of Paré and Guillemeau to the present time, the belief has prevailed that certain substances possess a specific power over the actions of the uterus, and promote labour pains. Oil of cinnamon was used by Chapman, and I believe he had great faith in it. In Brachen's time the same opinion was very generally entertained, but he did not believe it to be true. Ergot appears to have been employed by midwives on the continent from time immemorial. Desgranges published his first researches on its properties in 1777, and they have since been examined by several American and French physicians. The results of all the observations hitherto made upon the *secale cornutum* prove that it does in some cases of labour excite the contractions of the uterus in a very peculiar manner, but that its action is extremely uncertain, and that it often fails to produce the slightest effect. Some deny that it possesses any influence whatever over the uterine contractions; but there can be no doubt that it occasionally does act upon the uterus, and very violently.

As it is impossible to determine in many cases the precise cause of the difficulty in protracted labour, to be sure that the restrained uterine contractions do not depend on some unusual condition of the contents of the uterus, and that the life of the child may not be destroyed by its use, I have never ventured, either in public or private practice, except in cases of accidental uterine hæmorrhage and retained placenta, to administer the ergot of rye to a woman in labour, and I am satisfied that no individual under my care has suffered from the want of it. But I have been consulted in many cases of protracted and difficult labour, where it had previously been administered, and in some I have not opposed its exhibition, where it has been firmly believed by other practitioners that it might be given with safety and advantage. Twenty grains of the powder have been given in a tablespoonful of warm tea, or warm water and sugar, and repeated three or four times at intervals of twenty minutes or a quarter of an hour. Or $\mathfrak{z}\text{ij}$. or $\mathfrak{z}\text{ijj}$. of the powder have been added to $\mathfrak{z}\text{vi}$. of boiling water, which has been allowed to stand for twenty minutes and then to be strained, and $\mathfrak{z}\text{ij}$. of this infusion have been given for a dose at intervals of a quarter of an hour. In other cases the decoction of ergot has been employed, or $\mathfrak{z}\text{j}$. of *this* preparation, called the liquor *secale cornuti*, has been repeatedly given, and one fluid drachm of which is said to be equal in effect to $\mathfrak{z}\text{j}$. of the powder. In the greater number of the cases in which I have seen it given, little or no effect has been produced upon the uterine contractions. But the

evidence of many others is so strong in favour of its decided influence upon the uterus during labour, that I believe it does sometimes, and in a striking manner, increase the labour pains. The pains produced by it are represented to be different from those nine-tenths of women experience in labour. The contractions excited by the ergot are unusually violent, they occur in rapid succession, so that there are no intervals between them, like those observed in natural labour.

It is agreed on all hands that ergot ought not to be given in first labours, as the rupture of the perineum would likely be the result; that it ought not to be administered in any case till the orifice of the uterus is fully dilated, the membranes ruptured, and the presenting part is ascertained. Nor should it be given in any case where there is a suspicion that deformity of the pelvis exists, or disproportion between the head and pelvis from any cause whatever. A foreign accoucheur has, indeed, recommended it to be given in cases of distortion of the pelvis, for the purpose of fixing or jamming the head of the child in the brim, in order that the long forceps might be applied over the occiput and forehead. But where distortion exists, or disproportion between the head and pelvis from any cause, I have never found that the *secale* was necessary to fix the head in the brim; this has generally taken place, more speedily than was desired, by the unassisted uterine action, and fatal contusion or rupture of the soft parts has too often been the result of attempting to deliver in such cases without lessening the volume of the head.

It would only be in such a case as the following that the ergot could be given without certain danger, and even in such a case I would prefer trusting to the efforts of nature, and the influence of other remedies whose operation is attended with less hazard to the mother and child. Suppose a woman has had previous labours—has a capacious pelvis—the os uteri soft and widely dilated, the membranes ruptured, the head presenting and low in the pelvis, no fever or inflammation, but the pains are feeble and irregular, and have little effect in pushing forward the head for several hours, and you fear exhaustion from longer continuance of the labour, and time, which you can ill spare from other professional business, is being consumed apparently to no purpose—under such circumstances you might be tempted to exhibit the ergot, and if you did so the probability is that it would produce no effect. But if it did act, and the child, which had been alive a short time before, was born dead, with or without the umbilical cord round the neck, you would then have good reason to regret that the case had not been left to

nature. If in practice you go about constantly armed with this weapon, as many midwives in London now do to my certain knowledge, you will probably be tempted to administer it in cases of protracted labour from great rigidity of the os uteri, hydrocephalus in the child, preternatural presentation, plurality of children, distortion of the pelvis, hæmorrhage from attachment of the placenta to the neck of the uterus, over distended urinary bladder, and other cases where the difficulty and danger are not removed by exciting the contractions of the uterus. *Secale* is certainly not a remedy which can be safely entrusted to inexperienced practitioners, or which ought to be prescribed in any case without the utmost caution. I have seen a number of cases of first labour, in which the ergot had been given largely though the os uteri was rigid, not more than half dilated, and the membranes unruptured; violent peritonitis followed in one of these. It was employed not far from this, in a case of protracted labour, where the difficulty arose from an immense accumulation of urine in the bladder; the bladder was ruptured, and the urine escaped into the sac of the peritoneum. I saw the perforated bladder soon after the occurrence, at the Middlesex Hospital, in the possession of Dr. Hugh Ley. It would have been employed in another case of difficult labour from retention of urine, which I saw in consultation not long after, had I not prevented it. In this case the head was so completely jammed in the pelvis that the catheter could not possibly be introduced into the bladder, and the urine drawn off, till the volume of the head had been lessened by perforation. I was called to a patient of the St. Marylebone Infirmary in 1832, who had been in labour nearly 60 hours, and was attended by one of the parochial midwives, who had given ergot liberally during the labour. The head was extracted with great difficulty after perforation. In 1833 she was delivered safely by the same means, but in 1834 she was attended by two inexperienced accoucheurs, who gave her the ergot of rye in great doses, without reflecting on the distorted condition of the pelvis. The vagina was afterwards lacerated by the forceps, and she died, soon after being delivered by the perforator and crotchet, with incessant vomiting and complete exhaustion. This is not the only case of distorted pelvis which I have seen where ergot has been employed. In other two the women died, and in a third there is an incurable fistulous communication between the bladder and vagina. In more than one case of placental presentation which I have seen, the ergot had been given before it was distinctly ascertained that the hæmorrhage arose from attachment of the placenta to the neck of the uterus. A gentleman

who had unbounded faith in the efficacy of *secale*, and who had prescribed it in a multitude of cases, met with one of protracted labour from congenital hydrocephalus, and here also his favourite remedy was vigorously applied; but the head could not enter the brim of the pelvis, and when the patient was completely exhausted I was requested to see her. A great quantity of fluid escaped on opening the head, which was afterwards readily extracted; but she died in a short time. Ergot was given in a case of difficult labour, from hydrocephalus in the foetus, which occurred a number of years ago in the neighbourhood of London, and rupture of the uterus was the consequence. In July 1836, a case of arm presentation occurred where ergot was given before the presenting part was felt. Great difficulty was experienced in turning. The child was dead, and the woman died on the 5th day. Not long ago it was given in a case of twins. The arm of the second child presented, and the utmost difficulty was experienced in the operation of turning.

It was observed in America that the children were often still born after the exhibition of ergot of rye, and this led many practitioners in that country to discontinue its use altogether. The same circumstance has likewise been noticed in this country, and it is not difficult to explain the cause. The contractions of the uterus excited by the ergot of rye are different from those of natural labour; they are of much greater strength and longer duration, like a number of violent labour pains continued into one another without intervals. The long interruption to the circulation of the maternal blood in the uterus and placenta, which must take place during these lengthened contractions, and the want of the necessary changes in the foetal blood, will explain why children are often born in a state of asphyxia, after the administration of the *secale cornutum*.

2. Of protracted and difficult labours, from a rigid and undilatable state of the orifice of the uterus, vagina, and other soft parts.

It is in first labours, and in women advanced in age, that rigidity of the *os uteri*, and other soft parts, is most frequently met with. Sometimes it is confined to the orifice of the uterus, so that the second stage of labour is very short, when the first has been extremely protracted. More frequently the rigidity exists both in the orifice of the uterus and in the parts at the outlet of the pelvis, so that the first and second stages are both tedious and painful. In the greater number of cases of this description, if no improper treatment be employed, the dilatation of the *os uteri* and other parts is at last accomplished with safety to the mother and child. It is necessary, however, to be fully

aware that both are exposed to imminent danger if the labour is protracted from rigidity beyond a certain period; and every practitioner ought thoroughly to know the symptoms which indicate that the labour has been left to nature, or allowed to continue as long as is compatible with their safety.

The parts after a certain period become hot, dry, swollen and puffy, from the long continued pressure and interrupted circulation, and so tender that an examination cannot be made without causing pain. The discharge from the vagina becomes offensive, and retention of urine takes place from the pressure of the child's head on the urethra and neck of the bladder, with a sense of soreness and tension of the abdomen. More or less anxiety should always be felt about a case of protracted labour where any of these local symptoms are observed, and especially where the employment of the catheter becomes necessary, and where some difficulty is experienced in passing it into the bladder, and where the head of the child has remained several hours without making any progress, and the bones are compressed, and there is a large tumor under the scalp. The excitement of great constitutional disturbance, with increased determination of blood to particular organs, especially the brain, and exhaustion of the vital powers, are the most unfavourable general symptoms observed in cases of protracted labour from rigidity. The accession of fever in the second stage of labour, or in the first stage after the membranes have long been ruptured, indicated by rigors, a rapid pulse, furred tongue, and flushed countenance, affords additional evidence that the labour cannot be left much longer to the natural efforts; and still more unfavourable is the case if the labour pains have been gradually diminishing in force, if the head has ceased to advance, and symptoms of exhaustion have appeared. One of the most striking circumstances observed in these cases is the sudden manner in which the unfavourable constitutional symptoms manifest themselves, and the necessity which arises for the immediate interference of art. The pains cease almost entirely, the head begins to wander, the face and trunk become covered with a clammy perspiration, the features and tone of the voice become completely changed—so altered that you might almost doubt whether it was the same individual you had been so long watching with anxiety—with constant restlessness and jactitation.

These local and constitutional symptoms may occur before the first stage of labour has been completed, but they are, perhaps, most frequently observed after the head has passed through the *os uteri* into the pelvis, and has remained there pressing for some time upon the parts at the outlet. While the dilatation

is going on, however slowly, and the head is descending, and none of these symptoms are present, the labour may safely be left to nature; but when the process is arrested, and the parts within the pelvis begin to suffer from the pressure, and symptoms of fever and exhaustion appear, it is your duty to interfere, otherwise the strength of the patient may be so exhausted that she will speedily die after delivery from the mere shock of labour, or from hæmorrhage and retained placenta, or, what is, perhaps, worse than death, she may have sloughing of the uterus, vagina, bladder, and rectum. There are few cases in midwifery which require greater practical skill to conduct to a happy issue than some of these cases of protracted labour from rigidity, and which are sometimes complicated with other causes of difficulty.

The most important remedy in cases of rigidity of the os uteri is, doubtless, venesection, which not only promotes the dilatation of the parts, but checks the disposition to inflammation and fever. If the patient is robust, the pulse full, strong, and frequent, and unfavourable symptoms begin to appear, especially congestion of the brain, the abstraction of a moderate quantity of blood from the arm is often followed by relaxation of the os uteri and external organs, efficient pains, and the speedy termination of the labour. In all these cases it is the most safe and powerful remedy we possess, and, if employed with proper caution, can never be injurious where the strength of the patient has not been previously exhausted by the long-continued efforts. You must distinctly understand, however, that blood-letting should be employed in no case of labour unless it is absolutely necessary, and that it is a remedy inapplicable to cases of disproportion between the child and mother, and where the protraction depends on feeble uterine action. Blood-letting during labour sometimes alarms the patient and her attendants, and is absolutely injurious by inducing debility in the puerperal state. Some practitioners have strongly recommended the exhibition of an enema of starch and laudanum in cases of protracted labour from great rigidity of the os uteri, after the employment of venesection.

Where blood-letting fails to relieve the symptoms, and artificial delivery becomes necessary, it may be safely completed with the forceps, if the os uteri is fully dilated, and the head has descended so far into the pelvis that an ear can be felt. Where the second stage of labour has not commenced, and the greater part of the head remains above the brim, and any circumstance occurs demanding immediate delivery, to save the mother's life the perforator and crotchet must be employed.

PUBLIC HEALTH.

An Oration delivered on the 70th Anniversary of the London Medical Society, on Wednesday, 8th of March.

BY LEONARD STEWART, M.D.

(For the Medical Gazette.)

THE most general and the most powerful influence exerted upon the constitution of men and animals is that of climate and locality.

Many familiar examples may be given of the force of the endemic causes of disease; which technical expression must be taken as including the telluric as well as the aerial agents prevalent in any given region, whose combined effect is to modify the living principle, and at times quite overcome the normal power of resistance to what is deleterious.

The production of agues in marshy districts; of goitres and cretinism in mountain passes; of dysenteries and liver complaints in various tropical plains; of fatal pestilential fever in other localities; the more familiar evils of scrofula, phthisis, and rickets, (called proverbially the English malady), all these, too surely, and too repeatedly, prove this assertion.

A comparison of the results of particular endemial influences gives us the means of escaping from danger, or of palliating the virulence of morbid agents, by removal to a locality having an opposite character. This mutual exchange of advantages is one of the most successful and gratifying arrangements in our power, for ensuring health and prolonging life; and one of the most reasonable in theory; because, in so doing, we remove the causes of evil, and prove the maxim that "prevention is better than cure."

The statistical information which is now being obtained from many quarters on the subject of medical topography is of the greatest importance in directing the migration of invalids, the route of all expeditions, and the establishment of colonies and new settlements.

It occasionally gives a reason for abandoning regions, which are either too severely cold for the susceptible natives of more sunny skies, or insupportably hot and pestiferous to the labourer from the north. It appears that any frozen climate develops tubercles in the Malay and in the negro; while we are told that the marshy plains of Demerara, though prolific of other diseases to the Anglo-Saxon race, are both preventive and curative of phthisis. There is some reason for believing that the causes of ague and consumption are antagonist powers, and do not commonly prevail in the same localities.

We have before us the good and the evil,

and can at pleasure use, without abusing, the natural influences around us.

Of course it will be recollected that, in speaking upon the subject of health and recovery from disease, the medical man is understood to consider them as objects of paramount importance.

He is not accountable for any obstacle that may lie in the way, connected with politics, commerce, or finance.

His vocation is to establish the laws of his profession, founded as they are upon nature and observation, and to disregard all other considerations but the discovery and declaration of the truth.

In the British Isles there appear to be no peculiar or indigenous diseases, if we except those already named, that are connected with the strumous constitution or diathesis. And even here there are other circumstances, which influence these maladies, if they do not originate them, that are not necessarily connected with our climate and locality.

On the contrary, it is our boast, in the present day, to be secure in the possession of a soil well subdued, and rendered incapable of generating the more noxious forms of malady; and of a temperature favourable to the development of the greatest energy of mind and body, unusually free from extremes of heat and cold, known as a general place of refuge from other malarious and plague infested climes. But notwithstanding our great natural advantages, and the addition of facilities resulting from enterprise and civilization, there does still exist a great amount of disease.

We have frequently wide-spread epidemics, and generally diffused contagious maladies; and the attention of the learned, of the powerful, of the charitable, has been from time to time aroused by the overshadowing of danger more than usually imminent.

The occasional prevalence of puerperal fever; the rapid march of scarlatina, small-pox, and certain eruptive diseases; the pestilential type of typhus in seasons of scarcity; the unexampled intensity and fatality of cholera; have all, in their day, called aloud for public consideration.

From a variety of causes, the desire for statistical and extended information has of late years been more fixed, and the facts already published and laid before the world, by official statements, as well as by individual declarations, have caused more deliberation than at any former period, on the possibility of affording relief.

When we ascertain that there are fewer malarious and atmospheric causes of malady with us than elsewhere, we at once establish the very important conclusion, that the circumstances which generate and diffuse the evils that do exist, are, in their essential nature, more accidental and artificial.

Our prevalent sufferings are therefore connected, it is probable, with modes of life and social conditions which are not incapable of reform. Such, for instance, as the precocious labour of children, and the sedentary occupations of females.

There is a great deal that can be traced to what is familiar and tangible—as to dirty and insufficient clothing, damaged provisions, over-crowded rooms, excessive toil, intemperance—often to ignorance and prejudice.

We cannot for a moment doubt, that by investigating and correcting these and many other improper habits of a similar character, much unmixed good may be done.

The many advantages which arise from “centralization,” and the collection of crowds into large towns and capitals, are not without great drawbacks.

The unnumbered conveniences and amusements, which attract equally the industrious and the frivolous, the cooperation for many common objects of business and pleasure, the multiplied choice of occupation, and the demand for the talents of the ingenious or the gifted, in ways unknown or unappreciated in rural life, the privacy, concealment, and mystery, necessary for many modes of existence (adopted by individuals, or forced upon their necessities), the greater liberty and variety offered to all classes, are too generally counterbalanced by striking disadvantages.

The masses have generally herded together without foresight, or due provision for comfort and safety.

This is especially the case in old and populous cities.

We have the narrow streets, dark and crowded passages, with noisome cellars and comfortless attics. There are the suffocating factories and workshops, the damp grounds and yards, the smoking labyrinths of what are called the “back settlements,” all swarming with the toil-worn, the debauched, and the brutalized, strangely huddled together. Their scanty or precarious food, dejection of mind, discomfort, ill-regulated or intemperate habits, and filthy places of residence, are altogether the prolific source of disease and infection.

The dangers arising from this want of arrangement, and the absence of the true conditions proper for health, relaxation, and natural recreation, are not limited to the labouring drudges, nor to the abject dwellers in low pauperized localities, but hang over, and frequently involve, those even who appear to be far removed and carefully secured from contact and contamination.

The intercommunion continually going on (however imperceptibly) between the members of any family, their children, domestics, and day-servants, with all the various dependents, messengers, providers,

and attendants, forms a chain of connection unbroken between the most epicurean and fastidious, and the most debased and outcast.

Innumerable examples could be quoted to illustrate this position.

It is quite impossible to live and move in society, and to be insured with anything like precision against the attack of some of the most pernicious and loathsome contagions.

*"Pallida mors æquo pulsat pede pauperum tabernas,
Regumque turres."*

There is a striking exemplification of this irresistible truth on record in the death of Louis XV., who, living in the midst of refinements and luxuries, with everything studied with a view to his health and security, after a long and voluptuous life, found his palaces and his parks no sufficient refuge from the terrible invasion of confluent small-pox.

It is for the good of all, then, to promote an improvement in the condition, both moral and physical, of the poorest and most abandoned :

It is twice blessed :

It blesseth him that gives, and him that takes !

In devising and in superintending all plans of medical police, our profession must cooperate with the legislature, the civil authorities, with the architect and engineer. We must call to our aid all the arts and sciences now rendered popular by civilization and enlightened government ; and join in providing due space for ventilation and draining, when they have been of old neglected ; or for additional comfort, cleanliness, and warmth, wherever these are demanded, in new districts.

Already it has been pointed out to the public, and to the proprietors of various works and handicrafts, that many of the desirable ends of skill and enterprise can be obtained at a diminished rate of suffering from noxious materials and from accidents ; but a great deal more is to be done under the personal superintendence of our profession, both by general precaution and the minute adaptation of ingenious contrivances.

Among crowds of people there are many things which oppose the full enjoyment of health ; but it is to be remembered there are some great advantages.

The very circumstance of their residing and acting together supposes more publicity and protection than when their work is done alone, and without assistants and witnesses. This particularly applies to children and young persons, who are often liable to suffer from neglect or tyranny where there is no one by to share their condition.

The forlorn and helpless situation of individuals or small families, when isolated and at a distance from help and attendance, is to

none better known than to medical men. It is well worth the attention of philanthropists, and those who desire the well-working of the social mass, to contrive some plan for the protection of children when their parents are away. The infant-schools, and other places of deposit during the day, are shut out from them when ill. The parents (whose occupation often keeps them abroad) are frequently obliged to employ very inefficient persons to supply their place ; or they have the difficult alternative of giving up their work, and forfeiting their only means of support. Even where there is no neglect, it is well known to those who are in the habit of attending the poor at their own homes, that there is too frequently great ignorance and prejudice, and that these helpless objects suffer from all kinds of mismanagement, injudicious meddling, and caprice. Add to all this, the danger continually arising from the number of persons huddled together in one room, frequently in one bed.

Under proper direction, it is probable that some plan of placing sick children under skilful and responsible persons when the parents are compelled to be away, or are incompetent to manage them, would diminish the intensity of the materials of infection, and prevent a great deal of mischief now arising from accident, ignorance, and at times from brutal inattention.

But it is not in cities alone (let it be understood) that our profession has to consider the best arrangements for health and well-being. In rural districts and remote settlements it is more than ever important that the presence of the medical man should witness the fulfilment of his precepts. It is here chiefly that neglect of authority, or blind adherence to custom, is found to prevail without chance of being corrected.

There are bodies of men, too, who are associated, but yet cut off, more or less, from ordinary intercourse with the world, and where the absence of an adviser and protector, with knowledge and influence sufficient to hold over them the shield of the remedial sciences, is felt as the greatest calamity. All rural factories, all mines and collieries, all asylums for the poor, the sick, the superannuated, the helpless, the insane, the captive, the criminal, look to us for fair play.

In an especial manner, as scientific men, we are called upon to be present with all expeditions and emigrations, by land or by water ; always as companions, and not unfrequently as leaders.

Whenever there is a probability of ameliorating the condition of labourers by regulating their work, both with regard to duration and intensity, or by insisting that the stupefying monotony of their toil should have due oppor-

tunity of being broken by amusement and heart-easing mirth, we should not be silent.

Whenever we can manage to save them from dangerous accidents, from deleterious materials, unwholesome places of work or of residence, it is the recognized province of our profession to interfere.

Who, so well as we, are entitled to open the door to moral and intellectual sources of improvement?

By no class is the intelligent co-operation of those with whom we have to deal more appreciated or more desired. We have unequalled opportunities for observation and reflection, and, as a consequence, I will boldly ask, where shall we find so little bigotry and prejudice?

I am not ignorant of the great attention which has already been given to many of these matters. I rejoice that much more is likely to be done in this direction; but I think it only right to say, that much more of the control and management of all sanatory regulations should be in the hands of medical men than has hitherto been common.

We have something more to do here than to set other people to work!

Our vocation is administrative as well as legislative: we are not only abstract advisers, but peculiarly and proverbially *practitioners*.

Medical men should be in person ready to superintend the execution of what they may theoretically recommend.

We have the highest *political* authority of the present day declaring that a physician should not prescribe until he is *called* in!

To suppose that there is an inherent virtue in *formulae*, that enables any one without education or practice to deal with them successfully, is really as absurd as to fancy that the colours and brushes of a portrait-painter constitute the chief part of his skill.

And yet this is common enough! It happened to me, some twenty years since, to be the only passenger in a merchant-ship; and upon the occurrence of some illness in one of the crew, I found the captain about to fire off some article from his medicine chest. I took this opportunity of examining this magazine of *specifics*, which consisted of a box of powders differently sorted—for in those days we had not got to infinitesimals! I was much edified at finding the simplicity and certainty to which the art and mystery of the practice of physic was reduced. There were some of these powders labelled as good for a fever, some for a spitting of blood, for a liver complaint, for rheumatism, and so on through the entire collection, which contained various antidotes for many other nautical maladies, both British and foreign. Upon my venturing to mention the possibility of his giving a wrong direction to

these compositions, (which he was in the habit of inflicting upon his men when slack at their work), and upon hinting that he ought to study diseases, and have some reason for his practice, my friend seemed to consider all this a troublesome refinement; as the names were plainly written, and he was not partial to innovations. I found, in short, that it was not easy to move him from the fixed groove in which his ideas ran, or to lessen his conceit of his own infallibility.

The experience of every day teaches us that it is precisely those who know least about anatomy, physiology, and pathology, who talk with the greatest confidence of the efficacy of various specifics, which they seem to consider as if *billeted* to certain maladies, or as so many charms or talismans, capable of producing results without any particular management.

They are deluded by names, and do not understand diseases.

Within my recollection the names and titles of mixtures, powders, and other preparations, were made to indicate the particular diseases and morbid conditions to which they were considered specially adapted. They were named from their supposed effects, and not from their composition and ingredients. This was at regular institutions, hospitals, and under the superintendence of educated practitioners. We have, however, made a great stride from this narrow and erroneous view of therapeutics. I do not know that, at present, any formulae are called after the maladies to which they are considered destined. Their aptitude or affinity is not declared; they are merely named by enumerating their ingredients or qualities. We now do not suppose that because certain drugs (by a peculiar affinity or pre-established harmony) are taken up by the stomach, as ipecacuan; or the intestines, as senna; or the uterus, as ergot of rye, so as to bear a part in modifying the functions of these organs, that therefore these medicines are always to cure the diseases of these regions. In short, we distinguish between the pharmacological and the remedial character of the various substances used for prescriptions.

The familiar titles of emetics, sudorifics, cathartics, diuretics, and so on, are retained more for convenience and classification than as indicating their invariable character. We know that, in the hands of the skilful, they are made to play various and opposite parts.

The past history of medicine shews that many articles of the *materia medica*, to which at one time great virtue and importance were attributed, have either sunk into total neglect, or are associated with other drugs, and are mere condiments or *adjuncts*. In this category stand most *spices* and aromatics. Many spirituous cordials,

whose names alone would indicate the possession of the most salutary influence, are now very often strictly forbidden in the very cases where they were once considered sovereign remedies. The names *aqua vitæ*, *usquebaugh*, *eau de vie*, and so on, in all languages were *Æsculapian* as well as *Bacchanalian* titles. But physiology is now in the ascendant, and we have discarded most of these old material notions.

In chemical and mechanical operations the action of the substances which meet is mutually balanced, and can be calculated upon. The result is unvaried and certain. There ought to be no irregularities, because these are purely physical experiments; they are of the exact sciences. It is only when the vital energy and organic power is called into play that there is any uncertainty or caprice, or that action and reaction is not reciprocal, and mathematically adjusted. This essential difference, it is very clear, cannot be attributed to the brute substance, the passive inanimate material; but at once marks the peculiar character of organization—the more active *initiative* and independent function of the living fibre.

There seems to be a discriminating power—a force which resists and repels the approach of deleterious matters, and their ingress into the absorbing surfaces. Again, it appears that this power is lost or modified, or possibly inverted, so that what was once excluded by the skin and mucous surfaces is, at these times, attracted and absorbed.

We continually observe the different susceptibility of various constitutions, or of the same persons at different periods, and in the many fluctuating conditions of health. We know that neither food, nor medicines, nor poisons, are acted upon in one invariable mode. Now the moral of all such researches is, that no routine can be established for all emergencies; because the true agents in all remedial transactions are the organs and functions of the living frame, and not the material appliances which are merely the occasions and instruments—the subject matter—of any change.

Too much stress cannot be laid upon this doctrine in our dealings with the public.

The study of the general laws of physiology, as well as a microscopic acquaintance with the most evanescent changes, and the practical application of this knowledge, fully entitle the conscientious practitioner to much weight and influence.

While we have so many fortunes made by hawking about a single recipe; so many laws amended by the development of principles familiar with us; so many characters rescued from aspersion by the display of pathological facts; surely those who stand at the source and fountain-head of all this good ought to be the most considered.

When acting in honourable alliance with all the sciences, keeping up with the march of discovery, and ever ready to suggest useful improvements, they leave behind them single-string practitioners, and the formalists, who adhere to narrow obsolete systems, who follow the *letter* but feel nothing of the *spirit* of their rules.

There is no doubt about the necessity for attending to the skilful preparation and to the dexterous administration of the most ordinary appliances and means, or of the importance of studying the relative and occasional utility of all palliative measures; but it is still more to the interest of the public that the superiority of thought and invention over dull routine should be made clear, and the agency of principles upon details understood.

Were attention generally paid to the natural history of diseases, no one would be satisfied with any single method of treatment; were it a popular conviction that the experienced reflection and vigilance of the practitioner should in every case be applied *before anything else*, there would be less reliance upon universal nostrums. Even in the boldest empirical or experimental attempts it would be seen that here also there should be a previous knowledge of anatomy, physiology, and pathology.

The plans of unenlightened people are always limited and meagre. They aim at a simplicity which is not borne out by observation and adhesion to truth; they fail, not only in candour, but in variety of resources. It is commonly true, that where they succeed it is by stumbling on a remedy; or still more frequently by claiming as their own what nature was about to do without them. On the other hand, it is certain, that when they are defeated, they are quite bewildered, having no reserve to fall back upon.

I am, for one, little disposed to quarrel with the boldness of any experiment, or the novelty of any theory or any practice; but I like to see the ground cleared, and the conditions well and fairly understood, so that no conclusion may be jumped at, and no victory unworthily trumpeted forth.

The exalted character and multiplied resources of intelligent medicine in its widest signification, would then be sufficient (without any interference from without) to bring into discredit the follies of quacks, and the culpable greediness of the dealers in patent medicines.

Many false promises made by reckless and unfeeling men would be contrasted with the good faith of the considerate adviser and faithful friend of the doomed and hopeless sufferer. Those who *kill* would stand out more distinctly from those who *cure*; and some daylight would be thrown upon the contrivances of those more crafty personages, who, making an even division between the

claims of their patients and their own profit, steer a middle course, give placebos only, and take especial care neither to kill nor cure.

But if an acquaintance with the natural history of disease, and the various sciences which are appealed to and put in requisition by the healing art, is necessary to the safe and successful practice of our profession, it follows that the unskilful employment of recipes by the ignorant, by amateurs, or by the followers of *routine*, is dangerous.

It becomes more and more important to supply the personal attendance and assistance of the skilful and experienced as generally and as widely as possible—to spread abroad not only the measures but the men. There can be no discovery, no conquest obtained by the skill or enterprise of our expeditions into various regions, more truly important than the sure victory established on all sides over the mischievous systems and ignorant practices pursued by various less enlightened people. This, although not always the object, is frequently the best result of such undertakings.

It must be consolatory to those who turn with pain from the contemplation of the violence committed when the customs of other countries are interfered with, or when their territory is invaded, to reflect upon the soothing and healing influence of the medical profession. Carried into all parts, and diffusing unnumbered benefits, it seeks, as the only tribute, information and experience—and this is collected and employed for the universal good. It is not always the same with the other professions.

We can well understand the dread and angry feeling which a vanquished and mortified nation may entertain against our naval and military heroes. Experience has shown that the spread of any new religion by persuasion and argument is always a work of time, when opposed by the bigotry of ignorant or interested persons. It is again conceivable that any proposal to fix an entirely new set of legislators and lawyers (with chancery suits and solicitors' bills) upon any people would not be acceded to with great alacrity. And the jealousy and rivalry of traders is always in the way of free and friendly relations with our commercial men. But the medical profession has, on every occasion, been met with confidence and kindness. Its good deeds and benevolent attempts are always hailed with feelings of profound interest, and remembered with gratitude. Syria and China will bear me out in this assertion! It is always something to counterbalance the evils too commonly attendant upon warfare and revolution, and to reconcile the conquered to the presence of strangers and innovators. It is one of the best ways, for all parties, of making compen-

sation. And this debt, which may be considered as due from a powerful and enlightened nation to the barbarians who fall under its sway, it is ever gratifying to contemplate; this is a kind of "national debt" which has indeed some chance of being redeemed.

So great are the resources of the profession, and such the energy and good-will of its members, that we could undertake to scatter on all sides from our "embarras de richesses," and to establish in all quarters the true principles and practice of the healing art.

This would be a twofold advantage; for the glut and stagnation which is so much complained of every where has its parallel in our province also. When we glance at the actual condition of all countries, we shall find that there are strange accumulations of similar conditions; so that distribution seems to be pointed out as the leading duty of the age.

We shall see, on every hand, multitudes existing in the position of the fabled Tantalus—surrounded by the most desirable objects, which they are debarred from using and enjoying. What numbers of persons, of all ages, sexes, and occupations, cramped by sedentary monotonous toil, when half asphyxiated in their close and dusty workshops, would fain escape to the breezes of the hill-side*. Many hunting tribes might safely share the excess of stimulants which the desponding artizan is now tempted to use, and miserably abuse.

We have a sister country exporting substantial food to all parts, yet half starving her own peasantry. In the wild parts of North and South America, the carcasses of deer and of cattle are left to rot, while many of our own labourers are limited to vegetable diet, or nearly so. The mountains of Switzerland are carefully cropped and shorn of every blade of grass; the wine countries are tended like gardens; while many of the richest plains, both of the old world and the new, as on the Euphrates and the Mississippi, are either abandoned or unattempted by the hand of the cultivator.

We have, at the present day, the eyes of politicians and of speculators directed to the striking spectacle of the Eastern coast of Asia (with its three hundred millions of Chinese, scantily fed, and often living in boats and on rafts for want of room on shore), as contrasted with the opposite North-west coast of America (or the Oregon territory), whose only civilized inhabitants consist of some few hundred men, the servants of two

* "As one who long in populous cities pent,
Where houses thick and sewers annoy the air,
Forth issuing on a summer's morn to breathe
Among the pleasant villages and farms
Adjoin'd, from each thing met conceives delight."

or three private companies of merchants. It is no far-fetched improbable theory, to propose the greater equalization of these opposite conditions.

"Nature's full blessings would be well dispens'd
In unsuperfluous even proportion,
And she no whit encumbered with her store."

We may imagine the many powerful elements of knowledge and production, which now jar and fret in opposition and competition, more harmonized and combined in effecting the general advantage.

In cities, in rural districts, in distant settlements, and in home colonies, it is still to be seen whether the peculiar good of each is inseparable from the usual drawback of evil to which each is now subject.

We may fancy such expeditions as have already occasionally taken place made more frequently and systematically, so as to encourage and hasten the progress of unsophisticated nations from barbarism to refinement.

What unnumbered benefits would arise to all, both far and near, from the solution of the great political problem, which proposes so to combine the results of intellectual and associated life, as to bring them to bear upon the rustic and the savage!

Already we have begun to act upon the plan of retaining the strength and creative power of large masses, without permitting the producers and operatives to be oppressed or neglected. We hear already a general desire expressed, that education for the mind, proper exercise for the body, and due repose and recreation for both, should be fully considered in all arrangements for associated life.

The diffusion of all kinds of publications now secures so great an interchange of intelligence as will prevent any isolated members of the human family from becoming torpid and indifferent to the attainments of the rest; and it is not an impossible thing to allow to the peculiarities of individuals much that the necessary order and discipline of the whole body can spare.

Should society, anxious to escape from some of the anomalous difficulties which have been before described, make a general movement on a more comprehensive scale, a speculation of such surpassing interest and importance would find no class of men who would more powerfully contribute to its success than our own.

The members of the medical profession form the truest bond of union between the near and the distant, the savage and the civilized world. We are the only cosmopolites!

There is no occupation which interferes so little with the free agency of others, and when it does command, accomplishes its end by

so often appealing to truth, and the laws of nature and necessity.

But in the promotion of any scheme of amelioration, I feel confident that nothing more than a generous emulation would animate our exertions.

I can safely assert, that as a profession we have at no time shown a disposition to claim more than our due. And, as the patriot of old (when not elected to some office, though conscious of deserving it), rejoiced that his country possessed men better than himself, we would gladly say to any people, or sect, or party, or profession, who should engage in this great work, who should take the lead in this glorious mission—

"Master, go on, and I will follow thee,
To the last gasp, with truth and loyalty."

CASE OF DIABETES MELLITUS,

WITH NUMEROUS OBSERVATIONS,
AND A REVIEW OF THE PATHOLOGY AND
TREATMENT OF THIS DISEASE.

By JOHN PERCY, M.D. (Edin.)

Physician to the Queen's Hospital, and Lecturer
on Organic Chemistry at the Royal School of
Medicine and Surgery, Birmingham.

(For the London Medical Gazette.)

It must be admitted that the hospital is the field where disease can be most minutely, most perseveringly, and most extensively studied. Hence arises the responsibility, which devolves upon every hospital practitioner, of exerting himself to the utmost in the promotion of the science of medicine or surgery; and the man who retains his connection with an hospital when he has become incapable, from one cause or another, of promoting this object, does not discharge his duty. The author is deeply impressed with this truth, and is desirous, so far as his humble abilities will permit, of contributing, in some degree at least, to the furtherance of medical science. Extended and correct observations are essential in every science, and, if in one more than another, especially in the science of medicine. Diabetes mellitus is a disease which, notwithstanding all that has yet been accomplished, either by observation or experiment, is involved in great obscurity. This fact is the apology for the publication of the present case. It is possible that multiplied and accurate observations may eventually shed some light upon the

pathology of the disease in question. Facts, at first apparently sterile and useless, have not unfrequently been found to admit of valuable and practical application. The case will first be minutely recorded; then will follow a variety of observations, intended to serve as the basis of reasoning; remarks upon the pathology, with the detail of some illustrative experiments; and, lastly, a review of the various methods of treatment which have been recommended. The author can truly declare that he has had but one object in view, and that is the elimination of truth.

Joseph Merchant, æt. 31, admitted in-patient of the Queen's Hospital, August 25th, 1842. Of middle stature, and of moderately robust habit; complexion ruddy; hair and eyes brown. He has always been a remarkably temperate man. For the truth of this statement I did not rely solely upon the testimony of the patient, but upon that of persons who had long been acquainted with him. He was employed in attending to two steam engines connected with coal-pits; one engine was high-pressure, of twelve horse power, the other condensing, of thirty-six horse power. I am particular in relating these circumstances, in order that a proper inference may be drawn in respect to the atmospheric conditions to which he was habitually exposed. His average weight, when in health, was twelve stones and a half. He was married seven years ago, and has three children, of whom the youngest is two years old. Eleven months ago his wife died, and he has since been much distressed at the fact of his children being left motherless. Three months have now elapsed since the commencement of his illness. Before this period he had enjoyed uninterrupted health. He became affected with languor and depression of spirits; his appetite and thirst were inordinately increased; and he observed that he passed urine in much larger quantity, and more frequently, than natural, being obliged to rise several times in the course of the night for the purpose of micturition. From the nature of his employment, he has been exposed to very great and sudden alternations of temperature, to which circumstance he is disposed to attribute his illness. He has also, as might be expected, been accustomed to

drink copious draughts of cold water. The preceding symptoms have, in conjunction with gradually increasing debility and loss of flesh, continued to the present time. He has also lost all sexual desire.

Present condition.—His appetite and thirst are inordinate, and he prefers liquids cold. The skin is dry and slightly harsh; the tongue is fissured, red at the edges and tip, and coated in a slight degree in the centre; the gums are spongy and ulcerated round the teeth, and the saliva has an acid reaction. The mouth and fauces are dry, and he complains of a sour taste. The pulse is moderately compressible, and of the natural quickness. The quantity of urine passed will be found registered in the table appended to the case. The bowels are generally irregular and confined, and he is troubled with flatulence. The lower extremities are œdematous. His hair readily falls off, which was not the case previously to his present illness. He has neither pain in the head nor vertigo; both sides of the chest dilate equably; percussion is everywhere natural, respiratory murmur is generally feeble; he is without any cough or dyspnoea; there is nothing unnatural in the appearance of the penis; his sleep is not disturbed, except by calls to pass urine; he has inguinal hernia on the left side. He reports that, so far as his knowledge extends, none of his relatives were ever affected in a manner similar to himself; and this report was confirmed on careful inquiry of his mother. Before admission, he had been bled in the arm without relief.

Habeat Pil. Saponis c. Opio, gr. v. bis quotidie. His body to be sponged every morning with salt and water, and then to be rubbed dry. To have 12oz. of beef or mutton daily, with cabbage, and only a small quantity of bread and potatoes. To have infusion of chamomile for common drink. In other respects, ordinary diet.

August 28th.—Much as before. Pulse 76, soft.

Cont. omnia.

30th.—Complains much of languor and depression, and also of heart-burn. Bowels moved twice yesterday, and once this morning.

Cont. omnia.

31st.—Reports himself improved.

R Strychniæ, gr. j.; Sp. Vini Rect. f3ss. solve. Dein adde Aquæ, f3j. M. ft. mist. Capiat f3j. ex aquâ ter indies. Om. Opium.

Sept. 1st.—Reports himself better. Skin not quite so dry as before; œdema still continues; tongue red, and saliva acid.

2d.—He has evidently improved in appearance. Thirst somewhat diminished.

3d.—Last night he perspired freely during three hours. Bowels moved twice this morning. Pulse 84.

4th.—Has had pain in the bowels, with diarrhœa. Thirst abated; tongue red and moist; has not perspired; skin cool, and inclined to be moist. Pulse 80.

6th.—Has suffered from cramp and pain in the bowels during the night, and attributes this to the cabbage. It will, however, be seen in the sequel, that, for some time after admission, he was in the habit of swallowing by stealth even purgative mixture, placed in the ward for other patients, as he was ashamed of being observed to drink so copiously; and, when an opportunity occurred, he gladly drank water from the tap.

7th.—Reports himself improved. The cramp occasionally returns. He passes the greater part of his urine during the night.

Om. Mist. Strychniæ.

R Infus. Calumbæ, f3viiij.; Ammon. Carb. 3iss. solve.; Capiat f3j. ter quotidie.

Omit the cabbage.

10th.—Has not slept so well during the last two nights. Bowels moved regularly.

H. s. s. Pulv. Ipecac. co. gr. x.

R Tincturæ Capsici, f3ij.; Aquæ, f3viiij. M. Ft. gargarisma, subinde indies utendum. Cont. alia.

12th.—Thirst not so urgent; appetite as before; he feels better. Since he has taken the last mixture, he has discharged a considerable quantity of flatus; dryness of the mouth somewhat relieved; has had pain across the loins; no return of perspiration.

15th.—Thirstless; mouth more moist; he is drowsy, and much inclined to sleep.

19th.—Urinedischarged involuntarily

during the night; in other respects as before.

20th.—Passed a restless night.

R Calomelanos, gr. iij.; Pulv. Jacobi Veri. gr. v. M. Ft. pil. ij. h. s. a. Cont. alia.

21st.—œdema of legs and thighs increased; perspired freely in the night; he complains of pain extending down in the direction of the inner side of the thighs, and in those parts there is a diffused blush; abdomen enlarged, with fluctuation; bowels open; the redness, œdema, and pain described, continued several days. These symptoms, however, were much relieved by the application of cloths impregnated with acetate of lead lotion.

Oct. 4th.—Bowels moved four or five times daily. It would appear from the table that the quantity of urine passed daily is diminished in a remarkable degree; but, on inquiry, it is found that he passes some urine at the closet; still, the diminution is decided.

Mistura Cretæ, Tincture of Catechu, and Aromatic Confection, had been ordered during my absence.

7th.—His bowels have been moved six times during the night; thirst less; no perspiration; he passed about a quart of urine at the closet; tenesmus; tongue clean and moist; œdema of lower extremities has nearly disappeared; no abdominal fluctuation; no pain or tenderness of abdomen; pulse 70, feeble and compressible.

H. s. s. Pil. Sap. c. Opio, gr. x. formâ suppositorii. Cont. Mist. Catechu.

14th.—Feels better; legs less œdematous; bowels moved twice yesterday; wishes to have more meat.

Sumat. "Tannin" gr. ij. f. pil. ter die. 2 ounces of additional meat, and less bread.

18th.—Purging has returned: much complaint of languor and debility. The following mixture was prescribed in my absence, by the medical officer, Mr. Swain.

R Tinct. "Kino," Tinct. "Catechu," aa. f3ij.; Infusi Quassia, f3viiij. M. Capiat. f3iss. quartis horis.

22d.—Less purging; much as before in other respects.

R Sulphatis Ferri, Ext. Hyoscyami, aa. gr. ij.; Ft. pilula. Capiat j. ter die. H. s. s. Pulv. Antimonialis, gr. v.

24th.—Slept pretty well; had a suppository of five grains of Pil. Sap. c. Opio. Bowels not moved in the night; complains of looseness of the teeth, of weakness, and of pain across the loins.

Contr. pil. et rep. suppositorium.

Nov. 3d.—Improved; no return of purging; perspired freely in the night; pulse 84; somewhat improved in strength; slight drowsiness; no pain of head, or cough.

4th.—Perspired last night; tongue florid at the tip and edges; mouth dry; fæces dark and offensive, and containing, according to his own report, some blood; occasional pain across the loins; pulse 81, regular; counted during one minute while the patient was in a sitting posture; after walking three or four times across the room it rose to 84, counted in a standing posture. Respirations 22 in one minute.

℞ Sulph. Ferri; Camphoræ; Extr. Conii; Extr. Gentianæ; Extr. Rhei aa. gr. xij. M. Fiant. pil. xij.; Capiat. j. ter die.

To have three raw eggs daily, 4 ounces of additional meat, and 6 ounces less bread.

From the beginning of November to the beginning of January, when the patient expired, a register was accurately kept of the food taken, and the urine and fæces evacuated daily. These observations were made by an intelligent patient, who occupied an adjoining bed, and who was in every way qualified for the purpose, as he had long officiated as guard of the mail on the London and Holyhead road, and had, therefore, been accustomed to weighing. I am satisfied that this individual took every precaution to ensure accuracy of result. He scarcely ever left the patient Merchant, who could not, if he had been disposed, have deceived his attendant, in respect to ingesta or egesta.

9th.—Feels better. He relishes the eggs.

Contr. pil. Habeat ter die Sodæ phosphatis, ʒij.

12th.—As before; still some œdema of legs. Wishes to have an onion.

15th.—After exposure, he caught a severe cold, attended with pain of the

face and ear on the left side; he has, in consequence, fretted much, and to-day I found him crying.

℞ Sp. Ammon. Aromat. Sp. Lavand. Co. aa. ʒij.; Mist. Camph. ʒvss. M. Capiat ʒj. p. r. n.

I was sent for in the evening to visit him again. He complained of pain of the left side of the chest below the scapula, increased by pressure, by cough, and by deep inspiration. There was dulness in this situation, and the respiratory murmur was not audible over a limited space. Dyspnœa. Inspirations short and abrupt. I did not detect crepitation.

Lateri Sinistro Applic. Empl. Lyttæ.

℞ Sp. Æth. Nitr. ʒij.; Tinct. Opii. ʒiss.; Aquæ, ʒiv.; M. Capiat ʒj. p. r. n.

16th.—The blister has not risen; passed a tolerable night; no perspiration; pain of side diminished; dyspnœa relieved by the mixture; skin warm and dry; pulse 88, as before; bowels open last evening.

Rep. Pulv. Ipecac. co. gr. x. Cont. Mistura.

17th.—The blister having been left applied has now risen; no return of dyspnœa or of pain of side.

Rep. Pulv. Cont. alia.

23d.—Has been purged five or six times during the night; stools dark and watery; vesicular eruption of lower lip; when hurried or excited, he still has pain in lower part of left side of chest; skin dry, and more harsh.

Cont. Pil. Om. Sodæ Phosphas. Gargar. Boracis.

26th.—Feels much better this morning; perspired freely in the night; mouth less dry; spat freely last evening. Says that "when his mouth is dry he is always bad; and when it is moist he is always better." Bowels pretty regular; stools lighter coloured than previously.

Four eggs daily.

Dec. 6th.—I found him in bed crying, in consequence of severe pain referred to left shoulder.

Linim. Camph. Co. Potatoes to be omitted.

8th.—Still complains of aching pain,

referred especially to a small space on the posterior edge of the left scapula, where there is considerable tenderness on pressure; perspires much every night.

Cont. To have carbonate of soda daily.

9th.—Pain is removed from the scapula, and is now referred to left axilla; tenderness on pressure in the situation of the pain; tongue very florid at the tip and edges; mouth still moist; abdomen generally tympanitic.

Epigastrio applic. Hirudines iv. ; H. s. s. Pulv. Ipecac. co. gr. x. ; cras mane Olei Ricini, f5vj.

10th.—Passed a good night, and perspired copiously; tongue not quite so red at the tip and edges.

21st.—I had been absent for several days from Birmingham. Since I last saw him he appears to have remarkably altered for the worse. Complains much of wandering aching pains, referred to the shoulders, arms, and hips; feels much weaker; face œdematous; pulse feeble; dyspnœa, increased by the recumbent posture; numbness of both arms and legs; he cannot flex the fingers of the left hand; much purged.

Statim Habent. Suppositorium. c. Pil. Sap. c. Opio, gr. x.

R Infusi Calumbæ, Mist. Camph. aa. f3iv. ; Tinct. Conii, f3ij. ; Ammon. Carb. 5j. ; M. Capiat f3j. ; ter die. Diet as before. Om. alia.

24th.—Pretty much as before; complains of pain across the loins and shoulders; purging still continues; tongue aphthous; restless night; pale and offensive stools, compared to yeast.

Injic. Enema Amyli c. Tinct. Opii, f3j.

R Opii, Camphoræ, aa. gr. j. ; Ext. Hyoscyami, gr. ij. Ft. Pil. Capiat j. bis terve indies.

R Æth. Sulphur. Sp. Lavand. co. Sp. Ammon. Aromat. aa. f3ij. ; Mist. Camph. f3vss. M. ; Capiat. f3j. p. r. n. Gargarisma Mellis Boracis. Partibus quâ dolet. Empl. Opii.

28th.—Much complaint of pain and soreness generally, principally referred to shoulders, arms, and loins; no œdema of face; can scarcely bear to be moved; sat up nearly the whole of yesterday; purged five or six times during the night; stools dark; pulse compres-

sible; skin hot and dry; teasing hacking cough; slightest pressure about the shoulders occasions pain.

Cont. Medic. Sumat. Pil. 4tes. indies. H. s. Suppositor. Pil. Sap. c. Opio, gr. x. ; Lumbis applic. cucurbit. sine ferro.

R Extracti Conii. 3j. ; Aquæ, f3viij. ; M. Ft. lotio, partibus dolent. applic.

29th.—Much relief from dry cupping; purging six times in the course of the night.

Contr.

30th.—Passed a quiet night; perspired profusely during the night; he had had forty drops of laudanum. I found him asleep, bathed in perspiration.

Cont. et rep. haustus. Tinct. Opii.

31st.—Passed a tolerably good night; slept well yesterday and during the night; no return of perspiration, which, however, continued the whole of yesterday; pulse 98, compressible; occasional hacking cough; pains much abated; bowels moved last night; stools reported natural in appearance; tongue smooth and red; aphthæ gone; pain across the loins and between the shoulders; thirst much diminished; countenance more cheerful; mouth moist. Has, during the last four days, taken four opium pills daily; numbness of left hand and arm up to the shoulder; can now raise this hand to his mouth, whereas, a few days ago, he had scarcely any power over it.

Capiat Pil. Opii. v. quotidie. Rep. haustus Opii.

Jan. 2d.—In the afternoon of yesterday (Sunday), I visited him. He was much in the same condition as when I last saw him, except that the pulse was considerably weaker, and had evidently begun to fail. He took his opiate draught at about 2 in the morning. He voided urine for the last time at a quarter past 10 in the evening of January 1st, when he went to stool. Between 3 and 4 this morning he attempted to pass fæces, but without effect: at this time he drank copiously of peppermint-water, and was able to hold the bottle to his mouth. He passed fæces in bed at 10 minutes before 6, when it was found that he could not speak. After a few groans, he tran-

quilly expired at a quarter before 7 this morning. He sat up and was cheerful on the 31st of December. He fully believed that his complaint was removed, and that he should shortly be able to return to his friends, who, however, were apprised of his situation. Mr. Fulford, our intelligent resident-surgeon, informs me that for one or two nights previously to his decease he had obstinate erection, with sexual desire.

By some, perhaps, it may be thought that in recording this case I have entered into superfluous detail. My apology must be, that in the study of a disease like diabetes mellitus, the pathology of which is involved in so much obscurity, minute and persevering observation is essential. My object is truth; and I cherish the hope, that the labour and attention which have been expended in these observations, may tend, in some degree, to promote this object.

Post-mortem examination, Jan. 3, 10 A.M.: present, my colleague Mr. Bolton, Demonstrator of Anatomy; Mr. Fulford, Resident-Surgeon; Mr. Hinds, my industrious clinical clerk, and myself.

The body generally presented the appearance of great emaciation. No œdema. No cadaveric discoloration of depending parts.

Head.—On opening the dura-mater, on each side, a quantity of air-bubbles escaped. Examined the brain *in situ*. A minute quantity of effused liquid in the cavity of the arachnoid. Pia-mater of anterior lobes pale, but vessels of pia-mater of middle, and especially of posterior lobes, contained blood. On the anterior lobes, under the arachnoid, and *between* the convolutions, air, in small bubbles, was accumulated. On the posterior lobe of right hemisphere, on its upper surface, in the centre, and near the falx, there was a small quantity of white flaky deposit beneath the arachnoid in a few points; this matter appeared to be distinct from the membrane itself. On slicing off the hemispheres nothing abnormal was observed. A very small quantity of effusion was found in each lateral ventricle. The choroid plexuses were pale. In the arachnoid, at the base, there was also some serous liquid. The cerebralsubstance was everywhere firm.

Thorax.—On turning up the sternum, there came into view a superficial abscess, of an irregularly oval form, and about two inches by three, situated on the anterior and inferior part of right lung, and commencing at the cartilage of the third rib and extending to that of the sixth. Immediately beneath this abscess the lung was condensed, and there were several small excavations containing pus; and further in the substance of the lung were found several small collections of softened tubercular matter. Slight pleuritic adhesions on the right as well as the left side, but to a greater extent on the former than on the latter. Right lung weighed 2 lbs. (all the weights avoirdupois); left lung, 1 lb. 1½ oz. Both were gorged with red serous liquid, and both contained small collections of tubercular matter, in a crude and also in a softened state, irregularly disseminated throughout their substance. Some of these collections, of the size of a small hazelnut, were immediately beneath the pleura. No pleuritic effusion. *Heart* small, weighing, with the arch of the aorta, 8 oz. 12 drachms. On the surface was a quantity of gelatinous matter, which appeared like translucent fat*. All the valves and all the cavities perfectly natural.

The vagus nerve was very large and firm. The great and lesser splanchnic nerves and semilunar ganglion were much larger than natural; and these nerves were so firm as to appear to the touch cartilaginous and chord-like. Thoracic duct of the natural size. The muscles of the chest, and, indeed, the muscles generally, were pale and flabby, and in some parts, for example the recti abdominis, had undergone a kind of gelatinous degeneration.

Abdomen.—No liquid in the peritoneal cavity. The intestines were pale and attenuated; they were generally stained with bile, and where they were not so stained they presented a pale leaden hue. We were remarkably struck with the almost complete absence, in the omentum, mesentery, and the body throughout, of everything that resembled ordinary fat. Except

* This matter became opaque by boiling in water. Æther extracted only a trace of fatty matter. By drying, a minute quantity only of residuum was obtained.

in a space of small extent, the omentum had a dark slaty appearance, as though produced by a kind of melanotic deposit. The mesenteric glands were generally enlarged, and, by section, exhibited a somewhat gelatinous aspect. *Liver*: Gall-bladder distended with pale bile. Colour of the liver natural. Some adhesions on upper surface to the diaphragm. Nothing abnormal discovered by section. Liver and gall-bladder weighed 3 lbs. Spleen apparently healthy; weight 6 oz. *Pancreas* also healthy; weight 3 oz. *Stomach* presented nothing abnormal. *Kidneys*: *right* weighed 6 oz. 5 drs.; *left*, after having been injected with size, weighed 7 oz. 8 drs. Both were more deeply lobulated than usual. They were equal in size. *Right* measured $4\frac{1}{2}$ inches long by $2\frac{1}{4}$ broad. On

the surface of the *right* one there were collections of what appeared like caseous matter before section; they were eight in number, varying in size from a pea to a hazel-nut; they were scattered irregularly. By section it was ascertained that they contained true purulent matter. There was no proper fat in the vicinity of the kidneys, but only a substitute of the same gelatinous consistence as that formerly described. The infundibula and calices were all, as might be anticipated, much larger than in ordinary circumstances. The *bladder* was distended with urine of a brown colour. I collected f xxij .; some, however, escaped on removing the viscus. No morbid appearance. A small collection of pus was found in the vicinity of the prostate.

Table of the quantity of Liquid drunk, and the quantity of Urine evacuated daily, from August 29th, to October 20th.

The first part of this table is doubtless, in some respects, incorrect, from the fact, previously mentioned, that the patient for a short time after admission took liquid by *stealth*. He confessed this a few days before his death, but affirmed that afterwards he had never deceived us in this respect.

Tables of the quantity of food, liquid and solid, taken by Merchant, from November 2 to January 2 inclusive.

Every single item is introduced, in order to furnish data for any calculations for which these tables may serve as a basis. Dinner means 14 ounces of meat, beef or mutton, cooked; the extra weight is gravy and potatoes. The average amount of gravy may be ascertained by reference to the latter part of the table, when no vegetable matter was taken with the meat. Supper means simply milk. The milk used for tea is included in the supper. The weights are avoirdupois. For gin was occasionally substituted whiskey. 1000·0 grains of beef-tea were found to contain 931·6 of water, 52·8 of animal matter, and 15·6 of saline matter. Peppermint water was common water flavoured with oil of peppermint.

THE
HUMAN SKIN AND ITS
PATHOLOGY.

By OTHO WUCHERER, M.D.

Member of the Royal College of Surgeons in
London; Rua de Boa Vista, Lisbon.

(For the London Medical Gazette.)

THE following brief and cursory sketch of the anatomy and physiology of the skin and mucous membrane, is intended merely as a preface to some remarks on cutaneous diseases, and professes to regard only some of the more recent discoveries.

Corium and mucous membrane resemble one another much in structure: in respect of chemical composition, however, they differ; the former giving glue when boiled, the latter not. Both have some resemblance to cellular tissue, consisting of fibres united together to a sort of irregular net-work, but they are easily distinguished from it by a granular appearance, and a more intricate interlacement of their fibres, which have, however, between them an homogeneous structure, bearing a greater resemblance to that tissue. Mucous membrane contains, moreover, as pointed out by Henle, dark bodies equal in diameter to 0·0013 of a Parisian line, of an uncertain shape and unequal distribution, soluble in acetic acid.

The corium presents on its surface slight elevations, the diameter of which is found to be equal to half a Parisian line. They consist of tortuous vessels,

and loops of nerves, and seem to be connected with one another at the base: however, they are evidently separated by perceptible grooves; they are pierced by the excretory tubes of the sudorific glands. As in other parts, two and two primitive nervous fibres form loops, but in the elevations now in question these loops do not lie so open to view, being folded together in various ways, so as to form balls, some of which, collected together in the figure of rosettes, may be found on the corium of the ends of the fingers, as shown by Gerber.

Leuwenhoeck long since described, as consistent parts of the skin and epithelium of the mucous membrane in the mouth, pentangular scales, which are constantly cast off from the surface and reproduced underneath: however, Henle was the first to give a proper description of the superficial coverings of the skin and mucous membranes, to which the term of epithelium is applied in common. According to this assiduous anatomist it consists of one or more layers of transparent cells, which cover the corium, in a great part the mucous membranes, the serous membranes, and also the inner tunic of the blood-vessels. These cells have a nucleus, the shape of which is more or less flat and roundish or oval, and in which again are discovered one or two nucleoli. The shape of the nuclei is always the same, but not so that of the cells, which differs in the different kinds of epithelium, as also in the different stages of their development.

The first kind of epithelium described by Henle has in its appearance some resemblance to the pavement of a street; whence the German term, *plaster-epithelium*, for it. It forms a covering for the whole surface of the body, and some parts of the mucous membranes. The cells of which it is composed follow in general the outlines of their nuclei, which they surround as spacious cases. Acetic acid sometimes dissolves only the cells, or only their nuclei, or both, or neither. In all parts, except the excretory ducts of glands and the tympanum, they lie in more than one layer. As they proceed from the surface of the skin propelled by new generations of cells, and so gain at last the outmost position in the whole layer of epithelium, they undergo changes in their structure and shape, arising from their pressure one against the other.

In the layer next to the corium the nuclei are of a yellowish red, and have a slight resemblance to blood-globules; in the beginning they are not surrounded by cells, and when these appear they surround the nuclei very closely. Of this layer acetic acid dissolves both nuclei and cells. In the next more superficial layers the nuclei show a more granular appearance, are of a lighter colour, and appear larger; however, the cells grow still more, and become, in proportion to the nuclei, much larger than in the preceding layer. Still more superficially both cells and nuclei become flatter, till they finally attain the shape of thin scales or disks with their nuclei in the middle. The nuclei become, as the cells proceed to the surface, less and less distinct, particularly when the latter dry up and stick together. The diameter of the nuclei in this kind of epithelium is 0.0012-0.0040 of a Parisian line; that of the cells in the innermost layer 0.0035-0.0072; in the most external or superficial layer 0.010-0.015 of a Parisian line. The thickness of the epithelium never diminishes, and as the most superficial cells are cast off there must be a constant reproduction of cells on the corium. These new cells undergo, then, those changes in structure and shape, as are described above in the different layers of cells. According to Schwann, the nuclei of new cells are formed in a fluid substance, which being the same in which all tissues have their origin, is called by him cyto-blastema. This kind of epithelium, as at present described, covers besides the corium some parts of the mucous membranes. The mucous membrane of the eyelids has, according to Henle, cylindrical epithelium, but the lachrymal tube has pavement-like epithelium, which reaches on the septum, as well as on the side-walls of the nose, till to a line which you may imagine extending from the anterior free margin of the nasal bones to the anterior spine of the superior maxillary bone. The tympanum is also laid out with a pavement-like epithelium consisting of very small globular cells. In the neighbourhood of the larynx, the ligaments between the tongue and epiglottis, the upper surface of the latter and the posterior part of its under surface are covered with pavement-like epithelium. On the anterior wall of the larynx it reaches but a short way under the epi-

glottis, on the posterior till about two lines from the aperture of the larynx. Beyond these limits, another, the vibratory epithelium, is found. On the mucous membranes of the digestive tube the pavement-like epithelium is extended over the inside of the mouth, over the pharynx and œsophagus, till to the pylorus, meeting, however, at the cardia with a short interruption. On the uropoetical mucous membrane of the male, pavement-like epithelium is found only in the cells of the prostate, and in the vesiculæ seminales; in the female it covers the inner surface of the labia majora, the nymphæ, clitoris, hymen, vagina, and inferior half of the neck of the uterus.

The second kind of epithelium, as Henle describes it, is the cylindrical epithelium. Its cells are of a conical shape, the point being turned towards the mucous membrane, the base towards the surface, and the nucleus situated about the half of their length on the inner surface of their wall. These cylindrical cells become immediately pale in acetic acid, and after some time they are dissolved by it to the nuclei, which finally also disappear. Ether or alcohol produce no change on them, nor carbonate of ammonia or caustic ammonia, and the strong mineral acids, but they are soluble in carbonate of potash and caustic potassa. Their length is equal to 0.008-0.009 of a Parisian line, the diameter of their thick end to 0.0017-0.0024 of a Parisian line. This epithelium is not constant like the former, but at intervals cast off and reproduced. According to Henle it is found at a point in the stomach just below the cardia, and then from the pylorus till the anus throughout the intestines, covering all the projections. At the anus it stops suddenly, and there is no gradual transition from it to the epithelium of the skin or epidermis. It covers also all the excretory ducts of the glands connected with the digestive tube. In the genital organs of the male it is only wanting in the prostate and vesiculæ seminales. The urinary bladder has an intermediate kind of epithelium, with oblong cells placed perpendicularly.

As a third kind, Henle describes the vibratory epithelium, which consists of cylindrical or conical cells similar to those of the cylindrical epithelium, but they have on this broad end ciliæ 3 to 8

in number. The length of the cells is, according to Henle, equal to 0·008-0·0138; their greatest breadth at the external end 0·0037-0·0025 of a Parisian line. The length of the ciliæ is, according to Treviranus, equal to 0·0018; their thickness 0·0004 of a Parisian line. This epithelium is cast off and reproduced like the former, but at intervals. According to Henle it is found in the respiratory organs beyond the above-defined limits, and in the female genital organs upwards of the middle of the neck of uterus. It is also found on the inner side of the eye-lids, in the lachrymal sac and duct, and finally in the ventricles of the brain. The ciliæ are of an homogeneous structure, and are arranged in a manner similar to that of the lines seen on the palm of the hand. They move during life constantly to and fro, and bend at the same time in which the free ends of the ciliæ describe circles on their ends. A circular motion of the ciliæ, in which the free ends of the ciliæ describe circles, Müller and Rudolph Wagner declare never to have seen.

The nails and hairs may be regarded as a peculiar modification of the epidermis. The nails are received with their posterior part into a fold of the corium, which is, like this, covered with papillæ, differing from those of the corium only in being smaller. The structure of the nails is best seen in the foetus. If the nail of a full-grown foetus, or a new-born child, is cut through longitudinally, you perceive it to consist of several layers, the undermost of which are less distinct, particularly in that part concealed in the fold of corium, where they are hardly perceptible at all. This part of the nail is seen to consist of polyhedral cells, many of which show nuclei. Dr. Schwann thinks, that as these cells are pushed forward from their origin in the fold of corium by successive generations of cells, they attain the form of small flat discs, which are found in the front of the nail. But as in this case the nail would be much thinner in its fore-part than behind, Schwann, and also Lauth and Gurlt, are of opinion that the formation of cells takes place also on the under surface of the nail as far as it is adherent. These cells proceed towards the forepart of the nail, in which direction layers increase in number. Before the fifth month of foetal existence the

nail can hardly be distinguished in structure from the epidermis.

The hairs proceed from follicles, which according to Gurlt are nothing but impressions into or bulgings of the epidermis: this is clearly seen if the epidermis is torn off from a piece of skin of a foetus macerated some time; then these follicles are seen to come off in one continuation with the epidermis. They are widest at their blind end, and narrowest at their neck, or where they open on the surface. At their blind end they have an elevation into their cavity, similar to the bottom of a glass bottle; on this elevation the hairs grow forth. The hairs are, according to Weber and Müller, not round, but rather flat, and the surface they present when cut through is oval or reniform. Gurlt, Heusinger, Eble, Krause, and Valentia, declare them to consist of an external or cortical, and an internal cellular substance. The former is thin, transparent, and evidently of a fibrous structure; the latter is composed of cells arranged in a single row of a diameter equal to 0·0006-0·0015. In a hair are generally distinguished the point, the shaft, and the root. Gurlt says that in the point the cellular substance is wanting, but it is found in the shaft. In the root or bulb both cortical and cellular substance are soft and tender. The elevation on the bottom of the follicle is received into a conical cavity in the bulb of the hair, and Gurlt says that there intervene fine threads or roots between both.

Between corium and epidermis of individuals possessing a dark complexion is found the black pigment. It is contained in cells similar to those of the epidermis, which contain, besides a transparent nucleus, fine particles of pigment. Sometimes these cells are prolonged in three or more directions, and those prolongations that radiate from the central cell are also filled with pigment. Whether these cells of pigment proceed to the surface of the epidermis, like those of the latter, and undergo the same changes till they are cast off, is not yet ascertained.

Albinus* says, there are no sebaceous glands of the skin where there are no hairs, and rests this assertion on his own and Morgagni's observations: he did not fall very short of the truth, and

* Albinus, Acad. Annot. Libr. vi. c. 9.

would have been quite correct if he had said, where there proceed hairs from the skin there are sebaceous glands. However, there are but few places in the integuments where sebaceous glands are found without hairs, as on the prepuce and glans penis. According to the description of Gurlt, the sebaceous follicles are of an oblong oval shape, and consist of cells, which when void of sebum are transparent. The excretory tubes of these cells open generally two in number, into a hair follicle. The sebaceous follicles are disseminated throughout the whole integuments of the body, with the exception of the palm of the hand and the sole of the foot. In some parts they are more easily discerned than in others; they are easily recognised in the integuments of new-born children, particularly of the scrotum, where the absence of fat under the corium prevents their being mistaken for little particles of that substance. As long as the lanugo has not yet fallen off, they are distinct also in other parts. But they are also seen very well in the adult, in the integuments round the mouth, about the nose, and in the axilla. If the epidermis is carefully raised from the corium (after the piece of integument has undergone some maceration) in the direction the hairs proceed from it, fine white threads are seen to go from the epidermis to the corium; these are the sheaths of epidermis that extend themselves into the hair and sebaceous follicles. The latter are, as was observed above, connected with each other, but the hair-follicles reach into the subjacent fatty cellular tissue, and the sebaceous follicles extend but a little into the corium. These organs can be very well seen at the same time with the sudorific glands next to be described, in thin perpendicular slices of integument, for the excision of which some make use of a knife with two blades fixed in a parallel together, which can be screwed more or less close to one another according to the thickness of the slices you wish to cut.

The sudorific glands have been described by Breschet and Gurlt; they often extend beyond the corium into the subjacent fatty cellular tissue, and are in different parts of a different size; for instance, in the palm of the hand they are larger, and of an oval, in the

integument of the head more of a long shape. In man they consist of a long manifold-twisted colourless transparent tube. The continuations of these glands or the excretory ducts are wound in form of a spiral as they proceed through the corium; the thicker the latter, the greater the number of windings. For a clear view of these organs, as well as of the preceding, I refer to the translation of Rudolph Wagner's Physiology, by Dr. Willis.

The papillæ of the corium consist, as has already been mentioned, of tortuous vessels and loops of nerves. In parts where sensation is more acute, these papillæ are more numerous, and show a peculiar arrangement. Whether the skin receives motor nerves or not, is not clearly ascertained. Carus is of opinion, that the peripheric nervous loops are formed by the union of a motor and a sensitive nervous fibre. However, there are not sufficient grounds to set up such an opinion; besides, the auditory nerve presents also such loops at its places of distribution. If it was certain that the skin received only sensitive, and the muscles only motor nerves, this would assist us to decide the question: but Rudolph Wagner observes, that the skin possessed some contractility dependent on nervous influence, and that the muscles were not entirely exempt of sensation, as the pain attending spasms evidently proved. Supposing that the skin received both motor and sensitive nerves, a question not less difficult, perhaps, to decide than the preceding, would arise—if the nutrition of the skin depended on the former or the latter? Johannes Müller says, of such an influence of the nerves in general on nutrition, that we are much in the dark about it. Morbid affections, or an undeveloped state of the nervous centres, are not always attended by changes in nutrition: in other cases the extremities are flaccid and withered, and, what Müller considers a principal proof of the dependency of nutrition on nerves, there is a greater disposition to gangrene. Schröder van der Kolk observed, that in paralyzed limbs the muscular tissue was sometimes displaced by a fatty substance, and the arteries ossified. In cases where, from a defect in development, the nerve destined to supply an organ was wanting, this organ was observed to be wanting

also. However, it seems that the nerves are not indispensably necessary for nutrition, as is seen in the evolution of the ovum. But a nervous influence on nutrition is also not to be denied, as the experiments of physiologists, and daily experience, show. The question whether cerebro-spinal or sympathetic nerves possessed this influence is yet undecided: Müller says we know nothing to elucidate it, but that nutrition was not interfered with when cerebro-spinal roots were divided. Valentin says, in his *Repertorium*, 1838, that we know nothing certain about the influence of nerves on nutrition. To support the opinion, that nutrition was independent of nervous influence, one might make the remark, that the bones received no nerves (although their nutrition was evidently proved by observations and experiments, as, for instance, those of Mr. James Paget*) if it was not likely that small nerves encircling the arteries of the bones accompanied them; and this might lead them to the opinion, that since the sympathetic was the nervous system that supplied the blood-vessels, and the bones received only nerves with the latter, nutrition was regulated by the sympathetic. However, there is yet much to be investigated on this subject. Secretion and nutrition are evidently connected in one process. Müller says that few experiments had been tried for the direct proof of nervous influence on secretion, and confesses that we know little about it. He observes, that at first sight both cerebro-spinal and sympathetic nerves seemed to possess this influence.

The submaxillary and sublingual glands are supplied by the lingualis; the tonsils by the glosso-pharyngeus; the capsule of the knee-joint by a branch from the tibial nerve; and the mamma is supplied by the third and fourth thoracic nerves. However, Müller considers it probable that the cerebro-spinal nerves are accompanied by fibres from the sympathetic system. At all events, a dependency of the function of secretion on the nerves is evident in many cases of diseased brain or spinal cord: still, in hemiplegia of the one or the other of these nervous centres, the secretion of the skin is sometimes changed on one side of the body, but in others not. Those grey fibres found

by Remak in the sympathetic system, considered by him as nervous, were admitted as such by many physiologists, and amongst these by Müller, Schwann, and Henle, who went even so far as to consider them to be the nerves that rule the vegetative functions of the body. However, it is doubtful whether this structure is nervous at all. Valentin was the first who expressed himself against it; Volkmann and Bruns have latterly also denied their being a particular element of the sympathetic, and Rudolph Wagner seems convinced by their reasons. Valentin asks, if any one had ever seen grey fibres in the extremities of the adult. (*Repertorium*, 1840, Abth. i. p. 84.) And Henle, who, as we just mentioned, formerly adopted the nervous nature of these fibres (*Pathologische Untersuchungen*, 1840), has since changed his opinion, because they had no peripheric ends. If these fibres have no central (Valentin) and no peripheric ends, their nature must certainly remain problematical. Those who considered them nervous admitted only that they were nervous fibres different from others, perhaps less developed; and on this hypothesis was built another: this undeveloped state was to explain why volition had no power on the vegetative organs, and sensation in them was incomplete. Considered as the nerves for the vegetative functions of the body, they were called organic fibres; Krause called them *fibrillæ nodulosæ*, after their appearance. Rudolph Wagner declares them to be cellular tissue. It would lead us beyond our limits to treat here of the sense of touch; we must refer, in this respect, to the works on physiology.

From the surface of the corium the cytoblastema is secreted, in which there appear first the nuclei, and then the cells of the epidermis, as has already been described. The cells undergo a series of changes in form and structure till they are ultimately cast off. These changes cannot be considered but as taking place under the government of life, but they take place without assistance of vessels or nerves; they are in some degree, therefore, independent of the life of the individual; they remind one of the changes the cells of the yolk in the ovum undergo. The layer of epidermis next to the corium is

* Froriep's Notizen, 1839, 1840.

commonly called the rete Malpighi; and it contains, besides those nuclei and cells known as those of the epidermis, which are cast off, others that contain pigment, are of a peculiar form, and of which it is not quite certain whether they are cast off or not. This layer is as if interrupted in its continuity by the elevated papillæ of the corium, and hence the term "rete" for it.

[To be continued.]

ON THE INHALATION OF AMMONIA GAS AS A REMEDIAL AGENT.

BY ALFRED SMEE, F.R.S.

Surgeon to the General Dispensary, to the
Bank of England, &c. &c.

(For the London Medical Gazette.)

OF all the physical states in which bodies are known to exist, substances in the form of vapour or gas are most readily absorbed by animal membranes, producing rapid and powerful effects from very small quantities. As a mass, we are but little acquainted with the properties of gases upon the animal economy, and the little we do know is principally due to the persevering inquiries of Sir Humphry Davy. The rapidly deleterious effects of minute quantities of the vapours of hydrocyanic acid, of bromine, of sulphuretted hydrogen, and even of many other gases, exemplify well their powerful action on the animal economy. At present gases are almost entirely discarded as remedial agents, but doubtless there are numerous cases where substances may be advantageously employed as remedial agents in their gaseous or aëriiform state. Without wasting time upon general remarks, let me at once call the attention of the profession to a simple remedy of this nature, namely, the value of diluted ammonia gas for stimulating the mucous membrane of the mouth, fauces, trachea, and bronchi. By its local administration it may exercise its power over the whole system, as this gas may either be made to have a topical or general influence, according to the extent of its application.

The inhalation of so stimulating a gas as ammonia is well known to be, at first sight, perfectly startling to those who have never either tried it on their own persons or never seen it applied by others, but

it is really, in many cases, with proper management, a simple and one of the most delightful remedies that can be employed. If a bottle, containing a solution of the gas, as the common liquor ammonia or hartshorn, be opened, part of the gas escapes. If this comes in contact with the conjunctiva it stimulates it and causes much fluid to be poured from its secreting surface, and its influence on the delicate lining membrane of the nasal cavities is not less powerful. In fact, this vapour appears immediately to cause a secretion of fluid from the parts with which it comes in contact.

When this gas is absorbed by the mouth in far larger quantities, it appears to cause in a similar manner an increase of the watery part of the secretion, usually passing from all the several parts with which it there can come in contact. *A priori* it might be expected the glottis would resist the intrusion of the gas, but this is by no means found to be the case when in a diluted state, as it apparently readily passes into the innermost recesses of the lungs, and instead of producing disagreeable effects, causes sensations which are extremely grateful and agreeable. The gaseous nature of ammonia allows it to come in contact with every chink of the air-passages, and even the upper and back parts of the pharynx, which from its peculiar construction resists the application of other topical remedies.

The immediate effect of the inhalation of this gas is to cause the fauces and pharynx, before dry, and perhaps covered with inspissated adherent mucus, to force out a watery fluid to lubricate and relieve the membrane; the phlegm will then separate and come away, and a more or less instantaneous relief is frequently felt. We all know the expectorant qualities of ammonia, and the value of its sesquicarbonate, whenever the system will bear its administration, as a general remedy, but its qualities, when used as a local agent, seem to be more active in this respect than when used as a general remedy.

The most convenient mode of administering the ammoniacal gas is to use the vapour that spontaneously exhales from solutions of ammonia. Of these it is preferable not to employ a solution stronger than the liquor am-

monia of the shops, or weaker than the same diluted to twenty or thirty times its quantity of water. For general purposes, perhaps, the usual liquor may be employed diluted with ten times its bulk of water, but the strength of the ammonia must be regulated by the medical practitioner according to the nature of the case, and the susceptibility of the patient, and even according to the strength of the original liquor.

The liquor ammonia, diluted according to the discretion of the medical attendant, may be placed in a common phial, and as much should be inserted as to occupy about the two lower inches of the bottle. The patient has only to apply his lips to the mouth of this homely contrivance, and draw in his breath, when he will inhale a certain quantity of the ammonia. Before the application of the mouth to the bottle the patient should take care that none of the liquid adheres to the aperture, which on coming in contact with his lips would cause them to smart, and being no part of the cure, the pain would be perfectly useless. The number of inspirations to be taken at one time may be determined by the strength of the water and the effect of the remedy. Two, three, or four inspirations, will in general be sufficient at one time, but this must be repeated three or four times during the day.

A more convenient apparatus than the simple one last described may be readily made and advantageously employed. A bottle may be selected, and a cork procured, bored with two holes. Into one a piece of bent glass tube may be inserted, having the other end dilated for the convenience of applying the lips. Into the second hole of the cork a tube should be thrust, within half an inch of the liquid, so that when the patient inhales, the ammonia passing from the liquid tube is taken into the chest, and this is perhaps to be preferred to drawing the breath itself through the solution of ammonia.

Though the last apparatus will answer the purpose more or less efficiently, I have yet to describe a far more elegant device to be employed as an inhaling apparatus. A two-necked bottle is procured, as in the annexed cut; into one mouth a tube is adapted (*p*), to serve as a mouth-piece. This tube is ground to fit the neck, and when not

used is removed for the insertion of a common stopper (*s*), that the strength of the ammonia may be preserved. Into the neck another tube (*t*) is ground, into the inside of which another stopper is fixed (*s*). When the inhaler is in operation, this stopper is withdrawn to allow the air to pass into the bottle, but when not wanted it serves to close the apparatus. This inhaler is most admirably adapted for the desired purpose, and perhaps for gaseous inhalations cannot well be surpassed. The diluted liquor ammonia (*a*) is seen in the subjoined cut at the bottom of the vessel, extending to within half an inch of the tube.

The vapour inhaled from the liquor ammonia does not seem to pass away immediately, but may be distinctly tasted for some minutes afterwards, even subsequently to the commencement of its beneficial action. The value of the local application of this gas is seen in cases of what is called dryness of the throat, which appears to arise from a deficiency of the secretion of the liquid which normally lubricates the mucous membrane. The mucus from that cause becomes dry, and causes much uneasiness to the individual. The common and popular remedy of applying hartshorn and oil to the throat for various affections is probably in great part owing to the inhalation of the vapour of the ammonia, which necessarily at the same time occurs, as it is impossible that this external application can be effected without a large quantity being imbibed at the same time.

Ammonia gas is also beneficial in chronic hoarseness, especially in that which is often left as a sequela of influenza.

This gas affords great relief and comfort to the relaxed, swollen, and apparently semi-œdematous state of the mucous membrane, which supervenes from remaining in crowded, overheated, and ill-ventilated rooms, where every person not only inhales his own breath over and over again, but is under the infliction of breathing his neighbour's also. In cases of incipient cynanche tonsillaris it appears to be of much value if used at the very commencement of the attack; the slight impediment to deglutition, which is generally the first premonitory sign, is sometimes removed by one or two inhalations. There are occasionally cases of syphilitic ulceration of the throat witnessed, where the patient suffers from such debility that the practitioner is afraid of applying any remedy capable of depressing the system, where the inhalation of the gas might probably be of great service, but as such a case has not occurred in my own practice for a long period, I am unable to speak practically upon the matter*.

In old standing cases of asthma, especially in those in which the medical man considers that the internal use of the sesquicarbonate of ammonia is indispensable, in which the extremities are cold, the pulse feeble, and the general vital powers depressed, the local application of ammonia is particularly grateful, the patients feeling, as they describe it, a glow after its exhibition, and the warmth first imparted to the lungs extending by degrees over their whole system.

In cases where the patient feels a peculiar sense of contraction upon passing into cold atmospheres, as though the lungs resisted the intrusion of so unpleasant an agent, the inhalation of ammonia seems to quiet the spasmodic action, relieve the breathing, and give a comfort to the whole chest, which is delightful to the feelings of the sufferer.

Perhaps it is almost needless to notice that this remedy would be deleterious when either special organs or

the general system are attacked with acute inflammation, for there is but little doubt that the ammoniacal vapour is a decided stimulus, first locally in those parts with which it comes in contact, and, secondly, on the system in general, by its absorption into the circulation. As a stimulating agent it must obey the laws of stimulants generally. It should not, therefore, be employed when the part with which it comes in contact is inflamed, nor when a dry parched tongue, a full pulse, and a dry skin, denote a feverish system. In all chronic cases, or even occasionally with acute cases, with a feeble circulation, in fact, whenever the system is depressed, and stimulants are advisable, the inhalation of ammonia may be used with the greatest advantage and comfort to the patient.

I have made inquiries of those who have to deal with large quantities of ammonia, and are necessarily exposed to the inconvenience of a large escape of gas, but cannot find that even with extensive exposure it ever exercises poisonous or deleterious effects, nor does Ramazzini, in his curious little treatise on tradesmen's diseases, notice its action.

Not alone to the relief and cure of diseases is ammonia capable of lending its aid as a remedial agent, for it is an invaluable and effectual antidote to certain direct and powerful poisons. One of these poisons, the effects of which it thus counteracts, is bromine. This volatile fluid is perhaps one of the most deadly poisons with which we are acquainted. It lowers the circulation with great rapidity, and makes the action of the heart irregular, and unfortunately, from its volatile nature, cannot well be used without considerable escape. Its hurtful action on the animal economy is instantly counteracted by the vapour of ammonia, for when the two gases meet, dense white fumes are produced, when bromine probably ceases to exert its baneful influence, or at any rate only to a much less extent.* I

* The inhalation of ammonia might, perhaps, also perform the same good offices to syphilitic ulceration of the throat as cinnabar fumigation is known usually to effect. The use of the cinnabar, however, may be so much dispensed with by the antimonial and antimonio-ferruginous treatment which I have recorded (M&D. GAZ.), that the ammonia has not been used in any of these cases, but should further information be obtained upon this point, it will be the subject of a future communication.

* The production of these white fumes by the admixture of these two gases is interesting, and, so far as I know, has not been noticed by chemists, though I have myself long been in the habit of applying ammonia to distinguish between the fumes of bromine, iodine, and chlorine, the two latter elements having apparently not the same influence when brought into conjunction with ammonia. These white fumes are liable to be confounded with muriate of ammonia, if muriatic acid is present.

have known persons nearly poisoned by incautiously using this substance, and who have been quite at a loss to know how to proceed to neutralise its action. Those who have to deal with bromine would do well to have an open vessel of the liquor ammonia by their side, which is in general quite sufficient to prevent any unpleasant consequence, by combining with any bromine which may pass off in vapour.

Ammonia is also useful when prussic acid is floating in the atmosphere of a room, as in this case it not only neutralises the acid, but its stimulating properties are directly opposite to the depressing action of the acid.

As all bodies in burning give off ammonia, a consideration arises as to whether some of the effects of smoking may not be attributed to that agent independently of the active principles that substances used for smoking are known to contain. The possibility of such a thing has been suggested to me, but it is quite certain that only a small portion of the effects of smoking can be attributed to the ammonia. The presence of ammonia in a burning cigar may be shewn by collecting its vapour in a bottle containing a few drops of muriatic acid, when abundance of fumes arise. If liquor potassæ be added, the ammonia is again set free, and will again exhibit the white fumes if brought near muriatic acid.

There is an interesting physiological fact connected with the inhalation of ammonia, for in determining the lungs to increase their aqueous exhalation, it frequently at the same time causes a similar action on the skin by the exhalation of moisture from its entire surface. For the last two or three years I have occasionally been in the habit of inhaling ammonia as a luxury during the prevalence of the easterly winds, which by their action so dreadfully dry up and parch all living creatures.

The application of ammoniacal vapour, in the manner which has been already pointed out, is rather an agent of comfort, removing slight ailments and troublesome affections, than a remedy which is capable of saving life from violent diseases, except indeed when used as an antidote to certain poisons. Still, however, there is no complaint, however trifling, no system, however unimportant (if attended with

discomfort and inconvenience to mankind), that it is not the duty of the medical man to endeavour to relieve or remove.

No. 7, Finsbury Circus, London,
March 23, 1843.

ON

HÆMORRHOIDS OR PILES*.

By R. A. STAFFORD, Esq.

Senior Surgeon to St. Marylebone Infirmary,
and Surgeon Extraordinary to H. R. H. the
Duke of Cambridge.

(*For the Medical Gazette.*)

THE rectum (or straight gut, as it is termed) being the termination of the alimentary canal, and having the functional office of expelling the contents of the intestines after they have undergone the process necessary for the extraction of the nutritive matter to support the frame, is liable to many diseases, and these may be classed according to the structure in which they occur. The rectum is a continuation of the sigmoid flexure of the colon, and it is composed of two coats—the mucous or internal, and the muscular coat: at its superior part it is covered by a layer of peritoneum, but in the inferior portion it is not surrounded by that membrane, like the colon and the small intestines. It begins at and turns over the upper ridge of the sacrum, and at first is a little inclined from left to right, and then it becomes straight, and follows the hollow of the sacrum and os coccyx, being larger in volume at its termination. Its anterior portion is separated from the membranous portion of the urethra by a triangular space filled by cellular tissue, the superior portion of which corresponds with the prostate, and the inferior to the integuments of the perineum. The posterior surface of the rectum is covered by loose and fatty cellular tissue, which separates it from the levator ani and ischio-coccygeus muscles, and from the sacrum. The rectum is abundantly supplied by blood-vessels, there being large arteries going to it, and large veins returning from it, both of which are termed hæmorrhoidal. It has two muscles more particularly belonging to it—the levator ani, and the sphincter muscle.

* The substance of a lecture delivered at the St. Marylebone Infirmary.

The levator ani is destined to draw the rectum back after the expulsion of the fæces, and its fibres irregularly surround, and are attached to the gut, arising from the posterior part of the symphysis pubis, from the ilium above the obturator muscle, from the spine of the ischium, and from the fascia covering the obturator internus. The sphincter muscle surrounds the rectum at its termination at the anus, and arises from the fat and skin that surrounds the verge of the anus on both sides, nearly as far as the tuberosity of the ischium, and, by a narrow point, it is inserted into the perineum, acceleratores urinæ, and transversi perenæi muscles, and behind into the extremity of the os coccygis. Its office is to close up the rectum after the expulsion of the fæces.

Having, by way of introduction to my subject, given this brief account of the anatomy of the rectum and its appendages, I shall now speak of its diseases, and shall first treat on hæmorrhoids, or piles, the most common of them all.

Hæmorrhoids are an enlargement of the veins of the rectum, which become at first swollen and tense, and the blood contained in them remains coagulated, and thus a livid tumor is formed. At length, from the thickening of their coats, and from the coagulated blood contained in them becoming organized, they form excrescences on the internal surface of the gut, or at the verge of the anus. At first, their parietes are very thin, consequently they are apt frequently to burst, when they bleed very profusely, and are then termed *bleeding piles*. When they do not bleed, they have vulgarly acquired the name of *blind piles*. Hæmorrhoids are divided into internal and external, and they may be in various states of disease, each of which will require different treatment. They may be mere excrescences, when the only inconvenience they give will be their presence as foreign bodies: they may be inflamed, when they become very painful and swollen, looking not unlike a cherry; they may be in a relaxed state, resembling a half-dried red grape, and they may be ulcerated.

The causes assigned for hæmorrhoids are many. People of sedentary habits are the subjects of them; costiveness, by the pressure of the hardened fæces on the veins, will produce them; and any thing that may irritate the

rectum—for instance, a drastic purge, containing aloes, scammony, &c. I have known persons who have never had piles before take aloes and scammony, and they have been in such a state that they could hardly walk for them. Piles, I have no doubt, are, in some, constitutional and hereditary, and that they descend from father to son from generation to generation. I have frequently questioned those who suffer from them, and they have informed me that either their father or mother has been afflicted with them, and that the disease has been handed down to them as a family complaint. No doubt, in such instances, the rectum is naturally weak.

It has been observed that those who are affected by a disease of the liver are frequently the subjects of piles. This may be accounted for by the connexion the hæmorrhoidal veins have with the vena porta. The liver being diseased, the circulation of blood through this vessel is obstructed, and thus the hæmorrhoidal veins become congested. Any obstruction in the veins of the intestines will produce congestion of the veins of the rectum, and consequently hæmorrhoids: in short, whatever may impede the venous circulation of the viscera may give rise to this disease. Those who have diseases of the lungs, also, are frequently the subjects of hæmorrhoids and diseases of the rectum.

On examining many cases of hæmorrhoids which are presented to our notice, it could hardly be imagined that the excrescences which we see could ever have been connected with the veins; they are of so tough, hard, and even, in some instances, of almost a cartilaginous nature. I have seen piles so hard that their structure has resembled the gizzard of a bird when cut into; or have been not unlike the texture of brawn. No doubt the constant irritation, and the repeated attacks of chronic inflammation of the part, bring them ultimately into this state.

When an individual is subject to hæmorrhoids, the first symptom he experiences is a sense of weight and fulness in the rectum. Heat and pain supervene, which is frequently followed by bleeding when he goes to stool. The piles now protrude at the anus, and are of a lesser or greater size, sometimes being inflamed, and sometimes not. When they are internal, there is

pain in the sacrum, and a sense of weight and fulness high up in the gut. There is also considerable difficulty of voiding the fæces, constant straining, and tenesmus.

The treatment of piles varies according to the state in which we find them, and also whether they are internal or external. In simple piles, when they are external, and when there is no inflammation, laxatives internally, and astringents externally, are the best remedies. At first, perhaps, give a dose of castor oil, or an aperient of senna and manna, and sulphate of magnesia combined, or any other aperient, except aloes and scammony, which will answer the effect of relieving the bowels. After this order laxatives: such as the *Confectio sennæ* alone, or combined with potass. supertart, or sulph. sublim. and desire the patient to foment with the decoct. papaver alb.; or sit over a bidet of warm water. Apply a solution of liq. plumb. acet. dil. Use a cooling ointment, such as *cerat. plumbi acet.*, or if the hæmorrhoid requires being constricted, employ the *ung. galli*, the *ung. oxyd. zinci*, &c.; also, should they be in a relaxed state, desire the patient to use an injection of the decoction of the elm or oak bark, with the addition of alum in proper proportions.

In some cases it has been recommended by Sir Astley Cooper to puncture the pile with the point of a lancet, and squeeze out its contents. This should be done cautiously, for fear of hæmorrhage. In chronic piles the *confectio piperis* has been of great service, continued for some time. It appears to stimulate, and give a new action to the parts. If the piles are inflamed, then apply leeches upon them, or to the verge of the anus, using an evaporating lotion, a poultice, an opium injection, or an opium ointment, as the case may require, repeating all these remedies as often as they may be necessary. The diet is of great importance; it should be bland, and meat should be avoided. Gruel, arrow-root, puddings, macaroni, &c., is the best food.

The case before us is one of aggravated piles; so aggravated, that when protruded at the expulsion of the fæces, they are retained by the sphincter of the rectum, and cannot return with the bowel by the action of the levator ani; consequently they remain with that part

of the intestine to which they are attached external, and appear like prolapsus ani. In such a case as this none of the common remedies are of use. Aperients, laxatives, astringents, soothing ointments, Ward's paste, &c. may give temporary relief, but the only chance of cure is by their removal.

There are two methods of removing piles; by excision, and by ligature. When the pile is not attached to the intestine by a broad base, or is not internal, then excision is the quickest method of relief, but when it arises by a broad base, or is internal, then the removal by ligature is preferable. In Elizabeth Brown's case—Female ward, No. 2—excision answered very well, as the piles were external, and attached by a pedicle, but in the present case, where they are of immense size, there would be great danger of hæmorrhage; hæmorrhage of so fearful a description that the death of the patient might be the termination. I have seen hæmorrhoids removed by excision, where the bleeding was so great, that the surgeon has been obliged to remain with the patient for hours, employing ice, pledgets of lint, and styptics of every description, and it has been with extreme difficulty the bleeding has been made to cease. I remember some years ago assisting a surgeon of great eminence, of this town, who is now dead, to remove some internal piles from a naval officer of distinction. The operation was effected with great skill, but hæmorrhage supervened. Without exaggeration, I may say that at least a moderate sized chamber-pot full of blood was lost before it could be stopped. The surgeon expressed to me that he was never more alarmed in his life; so little control, for hours, had he over the bleeding. At length, by ice, pledgets of lint, and the exhaustion of the patient, &c., the vessels became plugged up by coagulation. I acknowledge the fearful hæmorrhage in this case determined me never to remove piles by excision unless I was certain no bleeding of consequence could occur; for although in six cases it might succeed, yet in the seventh the loss of life might be the result from this cause. Sir Astley Cooper, in his Lectures, mentions two or three cases where hæmorrhoids were removed by excision, and death from hæmorrhage was the result. One was in the person of a nobleman in whom two operations by excision

were performed. The first succeeded, but in the second hæmorrhage followed, from which he died. Sir Astley relates his case thus:—

“Five years ago a nobleman applied to me with internal piles. I was upon my guard in this case, and said I did not like to remove the piles without a consultation. A consultation was held, and the removal by excision was agreed to; I accordingly removed them, and he was well in a very few days. Two years after he sent for me again, and said that he had some more of these piles, with prolapsus ani, and that he wished me to cut them off again; I did so, and as I advised the recumbent posture he went immediately to bed. As I was anxious about this patient, I did not immediately quit the room, but stood chatting with him for a short time, when he said, I believe you must quit the room, for I must have a motion. I went out of the room, and upon returning shortly after I found him trying to get into bed, and upon looking into the vessel I perceived a considerable quantity of blood in it. In a few minutes after, he said he must have another motion, got out of bed, and again discharged a considerable quantity of blood. This he did four different times; one of the hæmorrhoidal arteries in the centre of one of the piles which had been removed was divided, and as I was determined he should not die of hæmorrhage, I said I must secure the vessel which bled, and with a speculum ani I opened the rectum sufficiently to see the blood-vessel, took it up with a tenaculum, and put a ligature round it. On the following day I found the patient, who was much advanced in years, extremely weak; he had had a severe rigor, he grew gradually worse, and in four days after he died. On examination of the body there appeared to be some slight disease of the intestines, but not sufficient to account for death; he was seventy-four years of age.”

In another instance, also, Sir Astley was asked to see a gentleman who had been operated on by another surgeon. The piles had been excised by the scissors, and the patient evacuated such a quantity of blood from time to time that he died in a few days afterwards.

He therefore, however the operation in some cases may be successful, was strongly against their removal by excision. From the experience I have

had I am of the same opinion. I have observed that when internal vessels are wounded, we have but little control over them; and this most probably arises from the warmth of the part, and their little power of contractility in comparison to vessels more external.

There are two modes of applying a ligature to hæmorrhoids; one by surrounding them at their base, the other by passing a double ligature through their centre, at their base, by a needle, and then tying each half separately. When the pile is not large, the first of these methods is best; but when it is the latter is preferable. Should there be any doubt whether the vessels supplying the pile can be strangulated by tying the whole base of the tumor, it is, better at once to use the double ligature. By doing so you will be certain of cutting off the supply of blood, and the hæmorrhoid must slough off; for by piercing the base at the middle with a double ligature, you immediately destroy the circulation through the vessels at the centre, and thus the death of the part is certain.

Before the operation is performed the patient should be desired to protrude the bowel, when the piles will be exposed. He will probably find it most convenient to lean forward on the edge of the bed, or to lie down on the side, to effect this object. Having ascertained the number of the tumors, and completely defined their base, you thread a curved needle, or a pile needle made for the purpose, with a double ligature. You then pass the point of the needle through the base of the pile: having done so, you cut the ligature and take the needle away, whereby you have two distinct threads through it: you now tie each thread tightly on each side of the base of the pile, and thus you completely strangulate the vessels supplying it. You treat each hæmorrhoid in the same manner, when in a few days they all slough off, and the bowel heals. Sometimes it happens that another crop of piles makes its appearance when the first you have tied disappears: this is owing to there being more left behind internally. Under such circumstances you must tie them in the same manner as the others were.

I shall now relate some cases.

W. Simmons, æt. 45, was admitted into this infirmary during the last summer, having a festoon of piles

round the verge of the anus, and internal piles of so large a kind, that, when he evacuated his rectum, the gut remained like prolapsus ani, and he was obliged to return it with his fingers, or it would have continued down. He had been in this state for some years. None of the common remedies could have been of the slightest service; consequently, as you saw, I tied these piles (six in number), in the manner I have described, and in a week they all sloughed off, and in a few days afterwards the man went away quite well.

The second case, which occurred in Captain C., was even worse than the last. He actually, from this disease, had been obliged to sell out and leave his regiment. One of you assisted me in removing these hæmorrhoids; and so numerous were they, that when the first crop which I had tied sloughed off, a second made its appearance, and was removed in the same manner. This case did remarkably well. I have frequently heard from the gentleman, and he keeps in excellent health, and since is married.

The third case occurred in a Mr. W., who was in one of the government offices. Being constantly obliged to sit, he suffered the greatest agony: at length he began to feel that he must give up his employment. He was a friend of mine, and consulted me upon his case. I told him he might get rid of his annoyance with but little trouble and little pain. He consented that I should operate upon him; I did so. In a week or ten days all the piles, which had been a source of vexation to him for years, dropped off, and he has never since had any return of them.

The fourth case was in a gentleman who had also an affection of the lungs. Independent of a cough and short breath, he was teased to death with ulcerated piles—so much so that there were very few chairs he could sit down upon. He was perfectly miserable. He had but little idea that any thing could be done to relieve him, so long had he suffered. He consulted me, and was surprised when I told him that, with but little trouble, his disease might be cured. He allowed me to tie ligatures round his hæmorrhoids, and in a fortnight he was well.

I have known cases of hæmorrhoids so bad that they have been the cause of preventing the individual from walk-

ing or riding. In one instance, a gentleman was extremely fond of shooting, but after he had walked one day he was attacked by piles to such a degree that he was obliged to give up the sport and lie upon the sofa. This was a source of great vexation to him, for he enjoyed the amusement beyond anything, and had excellent manors. He had employed all the palliative measures over and over again, but they gave him no permanent relief. Each time he went out, the next day he was attacked, and at length was forced to relinquish his favourite pursuit. This he had done for a year or two when he told me of his distressing situation. On protruding the piles they were of immense size, four or five in number, and in two of them their base was as large as the circumference of half-a-crown. He told me that every morning after he had gone to the water-closet, he was obliged to sit for half an hour, or more, to return them back with his fingers, and that he really was most miserable. I gave him my opinion that, however severe the case might be, yet if he would consent to have them tied in the manner I proposed, I felt certain he might get rid of this annoyance. He readily agreed to my proposal. Having prepared him for the operation, by giving aperients, &c. and ordering him moderate diet, I accordingly tied the piles. Not so much pain was experienced as might have been expected. In five or six days they sloughed off, but the surface of the bases of them were so great that it took some little time to heal them. In six weeks he returned home quite well. This was two or three years ago, I have both seen and heard from him frequently since, and he remains quite well, and pursues his favourite sport—shooting.

In another case, a gentleman of considerable consequence was excessively fond of hunting. He was, however, extremely afflicted with hæmorrhoids. Although he went out every day that he could with the hounds, he never returned home without being immersed in blood posteriorly from hæmorrhage; so much so, that it was remarked by the whole field. This state of things went on for a considerable time, when he consulted me. I found that the piles could be easily removed by ligature. The operation was performed,

and in a few days he got rid of what had annoyed him for many years of his life.

It is unnecessary to relate any more cases. All of these some of you have seen, either in the infirmary or in my private practice. I have neglected to mention a few circumstances in the treatment of these cases. In the first place you must take care to have the bowels well opened before the operation, which will be best effected by castor oil, the compound senna draught, or perhaps a dose of jalap, or what may best suit the patient. When the operation has been performed, and you are certain that the piles are perfectly strangulated, there can be no objection, if they are very large, and obstruct the passage of the rectum, to cut off their upper portion; for then no bleeding can take place. If there is great pain, a poultice may be applied, in a simple form, with the addition of Tinct. Opii. Having well opened the bowels before the operation, it is not desirable to give any aperient until the piles have sloughed off.

RESEARCHES

TENDING TO PROVE THE

NON-VASCULARITY AND THE PECULIAR UNIFORM MODE OF ORGANIZATION AND NUTRITION OF CERTAIN ANIMAL TISSUES,

NAMELY,

Articular Cartilage, and the Cartilage of the different classes of Fibro-Cartilage; the Cornea, the Crystalline Lens and the Vitreous Humour; and the Epidermoid Appendages.*

By J. TOYNBEE, Esq. F.R.S.

Surgeon to the St. George's and St. James's Dispensary.

(For the Medical Gazette.)

In the Introduction to this paper the author first speaks of the process of nutrition in those animal tissues which are pervaded by the ramifications of blood-vessels, pointing out the circumstance that even in them there is a considerable extent of tissue which is nourished without being in contact with vessels. The knowledge of this fact leads to the study of the mode of

nutrition in the non-vascular tissues, which are divided into the three following classes, viz. :—

The *first*, comprehending articular cartilage and the cartilage of the different classes of fibro-cartilage.

The *second* comprises the cornea, the crystalline lens, and the vitreous humour.

The *third* class includes the epidermoid appendages, viz. the epithelium, the epidermis, nails and claws, hoofs, hair and bristles, feathers, horn, and teeth.

The author then proceeds to show that the due action of the organs, into the composition of which these tissues enter, is incompatible with their vascularity. In proof of the non-existence of blood-vessels in these tissues, he states that he has demonstrated, by means of injections, that the arteries, which previous anatomists had supposed to penetrate into their substance, either as serous vessels, or as red blood-vessels too minute for injection, actually terminate in veins before reaching them; he also shows that around these non-vascular tissues there are numerous vascular convolutions, large dilatations, and intricate plexuses of blood-vessels, the object of which he believes to be to arrest the progress of the blood, and to allow a large quantity of it to circulate slowly around these tissues, so that its nutrient liquor may penetrate into and be diffused through them. The author states that all the non-vascular tissues have an analogous structure, and that they are composed of corpuscles, to which he is induced to ascribe the performance of the very important functions in the process of their nutrition, of circulating throughout, and perhaps of changing the nature of the nutrient fluid which is brought by blood-vessels to their circumference. The author then brings forward facts in proof of the active and vital properties of these corpuscles, and concludes his Introduction by stating, that it appears to him, that the only difference in the mode of nutrition of the tissues which contain blood-vessels and those which do not is, that in the *former*, the fluid which nourishes them is derived from the blood that circulates throughout the capillaries contained in their substance; whilst, in the *latter*, the nutrient fluid exudes into them from the large and dilated vessels that

* This paper was published in the Philosophical Transactions for the year 1841, of which the present is a brief abstract.

are distributed around them: and that in both classes, the particles of which the tissues are composed derive from this fluid the elements which nourish them.

The author then enters on an examination of the structure and mode of nutrition of the several tissues of each of these three classes.

In considering the First Class, the development of articular cartilage is described at great length during its various stages and at the different periods of life. Numerous dissections of the ovum and foetus are given in detail to illustrate the *first stage*, during which it is shewn that no vessels enter into the substance of any of the textures composing a joint, but that the changes they undergo are effected by the nutrient fluid from the large blood-vessels, by which each articulation is surrounded. In the *second stage* of the development of articular cartilage it is shown that the epiphysal cartilage is gradually hollowed into canals, within which blood-vessels are extended, which converge towards the attached surface of the articular cartilage; in this stage vessels are also prolonged over a considerable portion of the free surface of the cartilage between it and the synovial membrane.

In the *third stage*, that which is exhibited in adult life, the epiphysal cartilage is converted into osseous cancelli. These contain large and very numerous blood-vessels, ramifying throughout the whole of their cavity, and are separated from the articular cartilage by a very fine but complete lamina of bone, the articular lamella, which is composed of corpuscles, and

A vertical section of the inferior extremity of the os femoris, highly magnified.

A, The impervious layer of bone (articular lamella) to which the cartilage is attached, separating the latter from the cancelli.
B, The firm vertical fibres of the cancelli implanted into the upper surface of the articular lamella.

the author believes that the principal source of nutrition to the articular cartilage is the nutrient fluid eliminated by the large vessels of the cancelli, and which permeates the articular lamella. The free surface of adult articular cartilage is nourished by vessels which extend to a short distance over its margin, and between it and the synovial membrane.* It is quite certain that the

C, The blood-vessels of the cancelli.

vessels thus situated do not enter the substance of the articular cartilage, inasmuch as the arteries terminate in veins at the circumference of the latter. In this situation the arteries become continuous with the veins in the following ways: firstly, by their all ending in a single vessel similar to the terminal sinus in the vascular area of the chick, from which the veins arise; secondly, the arteries terminate in dilated cavities, which give origin to veins; and lastly, the two sets of vessels are directly continuous by means of loops of various characters: the apparent object of all these modifica-

* It is very probable that synovia, a highly animalized fluid, has some share in the nutrition of articular cartilages, especially as it appears that false cartilages, without having any attachment to the synovial membrane, are developed and grow floating in it.

tions is to cause a considerable quantity of blood to circulate slowly in the vicinity of articular cartilage.

The author points out the presence of fine tubes which pervade the attached portion of articular cartilage: to these he ascribes the function of transmitting through its substance the nutritive fluid derived from the vessels of the cancelli, and he also shows that articular cartilage becomes thinner as man advances in life, and that this change is effected by its gradual conversion into bone, a process which is always going on.

Fibro-Cartilages constitute the second tissue of the first class: they are divided

Vessels situated between the synovial membrane and the border of the articular cartilage of the condyle of the os femoris at the period of birth.

by the author into two classes; one comprising those which are not covered by a synovial membrane; the other includes those which have each surface lined by it. The structure of fibro-cartilage is carefully investigated, and in order to arrive at some definite conclusions on this subject, whereon anatomists of all ages have so much differed, he made numerous dissections of fibro-cartilages in the different classes of animals at various periods of their development, the results of which he details. He shows that this tissue is composed of cartilaginous corpuscles and of fibres; the latter preponderating in adult life, the former in infancy; and that during life the corpuscles are gradually converted into fibres. He enters at length into the question of the vascularity of these cartilages; and from a careful study of many injected specimens of man and animals at various periods of their development, the particular results of which he relates, he states that blood-vessels are contained only in their

fibrous portion: these have the function of nourishing the part that is cartilaginous, which, being subject to compression and concussion, does not contain any.

The Cornea, Crystalline Lens, and Vitreous Humour, are included in the Second Class of extra-vascular tissues.

1. The structure of the cornea is described as being very lax, and containing corpuscles only in a small quantity, mixed with bright fibres. The opinions in favour of its vascularity are combated, and it is shewn that the blood-vessels which converge towards its circumference are disposed in two different

ways: those which are the principal source of the fluid that nourishes it, and which from their position may be styled the sclerotico-corneal arteries, are large and numerous; they are situated in the substance of the sclerotic, and they converge to the point where this latter structure joins the cornea, in which position, without much diminution in their size, they suddenly become continuous with the veins that take a retro-grade course.

A second set, the conjunctivo-corneal arteries, pass over a small extent of the surface of the cornea, where they form a narrow band: the arteries terminate by forming loops with the veins, and do not penetrate the substance of the cornea.

Represents the vessels (conjunctivo-corneal) which pass to a certain extent over the surface of the cornea, between it and the conjunctiva.

A, The cornea; B, the conjunctivo-corneal vessels; C, the sclerotic; a, artery; v, vein.

2. The *crystalline lens* is described as being composed of corpuscles of which the radiating fibres are constituted. The arteria centralis retinae is the source of nutrition to this organ; it ramifies over the posterior surface of the capsule in the form of large branches; these pass round the circumference, upon the periphery of which they become straight, and terminate by forming loops with the venous radicles.

3. The *vitreous humour* does not present any traces of vascularity, and although many anatomists have in general terms represented the arteria centralis retinae as giving off in its course through the organ minute branches into its substance, still those who have paid especial attention to this subject have not been able to find such vessels. The author believes that the nutrition of this structure is accomplished by the vascular ciliary processes of the choroid, and that the

fluid brought by the latter is diffused through its substance by means of the corpuscles of which its membrane is composed, assisted by the semi-fluid character of the humour.

The Third Class of extra-vascular tissues comprehends the epidermoid appendages. The author describes them all as composed of corpuscles, which are round and soft where they are in contact with the vascular chorion, compressed and flattened where they are farther removed from it. He points out, in the substance of the hoof of the horse, the existence of fine canals, which he supposes to conduct fluid through its mass; and he states that the perspiratory ducts of the human subject possess a structure analogous to the spiral vessels of plants. The author describes each of the tissues of this class, and shows that the various modifications presented by the vascular system with which each is in contact have the sole object of enabling a large quantity of blood to approach and circulate slowly around them. He also points out, in connexion with this subject, the remarkable vital properties which are possessed by these non-vascular tissues.

In the conclusion to this paper, the author states that his object has been to establish as a law in animal physiology, that organs are capable of being nourished, and of increasing in size, without the presence of blood-vessels in their substance.

The application of the above-named law to the study of *Surgery*, in reference to the causes of the

extension of vessels into the extra-vascular tissues when in a diseased state, and to the measures to be adopted for the prevention and cure of those affections which are dependent thereon; and to *Pathology*, in the investigation of the nature of morbid structures, particularly of those classes which contain no blood-vessels, will, the author feels certain, be productive of scientific interest, and of practical advantage.

POST-MORTEM EXAMINATION IN A CASE OF SUDDEN DEATH.

To the Editor of the Medical Gazette.

SIR,

My attention has been directed to some remarks that have been made in the public journals upon the case of sudden death that has recently taken place in this village, and in which an imputation has been cast on the good faith of the parties who examined the body. As one of these individuals, I forward to you a statement of the circumstances, and our notes of the examination, for the purpose of placing on record the facts of the case, which have not yet, as far as I am aware, been fairly placed before the public.

I was hastily summoned, on the morning of Saturday, the 4th of February, to the shop of Mr. Pledger, a druggist, whom I found on the floor, supported by one or two individuals residing on the spot; a slight examination convinced me that he was dead—no lingering trace of vitality remained. The thought passed through my mind that he might have destroyed himself, and on looking round I saw on the mantel-piece of the adjoining room a phial labelled "Ol. Ess. Amygd.:" but as I could detect no smell of it when I examined the mouth of the deceased, I concluded that he had died from an affection of the heart under which he had often told me that he was labouring.

On Tuesday the 7th, a jury assembled to inquire into the circumstances attending his death, but as no suspicion was created in their minds, they recorded a verdict of "Died by visitation of God." So suspicious, however, was one member of his family, that his death had not been a natural one, that an examination of the body was after-

wards required; and Mr. Baker, a friend of the family, but a perfect stranger to myself, was requested to undertake it. Mr. Baker called at my house on the evening of the day after the jury had returned their verdict; and to his request, that I would assist him in the examination, I consented.

I enclose you the notes of the appearances we observed: they clearly reveal the cause of death, and are conclusive as to the object for which the investigation was undertaken. I pass no censure on the coroner and jury, but leave every man to judge for himself whether they performed their duty with intelligence and ability.

I am, sir,

Your obedient servant,

B. HANDS.

Hornsey, March 22, 1843.

Notes of the examination of the body of Mr. Henry Pledger, at Crouchend, Hornsey, on the evening of Wednesday, Feb. 8, 1843.

There was nothing peculiar in the external appearance of the body, nor any smell that excited suspicion. We reflected back the integuments in the usual manner, and, upon dividing the cartilages of the ribs, we first detected the smell of prussic acid; the further we proceeded in the examination the more obvious it became, till at length it was almost overpowering. The viscera of the chest were healthy. The heart particularly attracted attention, but nothing could be detected to account for his death.

The abdominal viscera were healthy; there was no trace of disease; and we remarked that, from the appearance of the organs, he might have lived to an old age. A ligature was placed around each orifice of the stomach, which was removed for further examination, though the odour given off left no room for doubt as to its contents.

The head was not examined.

Signed { James Baker.
Benjamin Hands.

We, the undersigned, certify that we were present at the examination of the body of Mr. Henry Pledger, that we were not aware of any peculiar smell when we entered the room where the body lay, but that whilst the examination by the medical gentlemen was proceeding, we became sensible of the

smell of prussic acid; that it became more powerful as they proceeded, and that from what we saw and smelt of the contents of the stomach, we consider there can be no reasonable doubt that he died from the effects of poison.

Signed { Thomas Comfield—Brother-in-law to the deceased.
Benjamin Baillie—Medical pupil.

N.B.—The stomach and its contents are in the possession of Mr. Baker.

SULPHATE OF QUININE.

To the Editor of the Medical Gazette.

SIR,

I OBSERVE in the MEDICAL GAZETTE of 6th January last, the following paragraph, without any observations attached. "Sulphate of Quinine. According to a Parisian journal (the *Examineur Medical*, of December 15th), serious symptoms, and even death itself, had lately followed the administration of large doses of sulphate of quinine in the hospitals." It would have been more satisfactory had an analysis of the salt been given, as we know that it is frequently adulterated. In confirmation, however, of the occasional poisonous properties of the sulphate of quinine, I find the following entry in my case-book, dated 1829. "Lloyd and Hackney, the one labouring under continued, the other bilious remittent fever. Exhibited the sulphate of quinine during the intermissions of the fever. In both cases an alarming syncope was produced; in the first after the exhibition of 48 grains, and in the latter of 42 grains. The average daily quantity given in both cases did not exceed 4 grains. The syncope easily yielded to cordials, and the usual means, but was attended with a peculiar feeling of annihilation. The drug was immediately omitted, and no evil consequence followed; on the contrary, health was rapidly established.

Of the influence of sulphate of quinine in producing the mercurial action.—John Pedley had suffered for 8 or 10 months previous to my seeing him, either from inflammatory action of the peritoneum, or some of the viscera of the abdomen, but I could get

no proper history of the case. He had been attended about three weeks by a medical gentleman, who, from the pain and tenderness of the belly, and white clayey colour of the stools, endeavoured by rubbing in and otherwise, to bring on mercurial action, but with very partial effect, for two days only procuring a slight alteration of the stools. It was about five or six weeks after this I saw him—a most wretched object, worn almost to a skeleton. He had great pain, puffiness, and tenderness of the abdomen, particularly in the region of the liver and of the hypogastrium, with scanty, irregular, and clay-coloured stools, weak and feeble pulse, and, in short, the case was a most miserable and hopeless one. Recollecting a practice I often followed of exhibiting mercury to detect collections of matter in the liver, which, when this is present, seldom salivates, and always weakens and injures the patient, I thought it not unlikely that this patient might have had the injurious effects of an injudicious use of mercury added to his original ailments; and partly with a view to recover him from this, and partly to try to give him temporary relief, I ordered him the sulphate of quinine, conium and hyoscyamus, with a little carbonate of soda, in the usual doses, three times a day. In the course of twenty-four hours his sufferings were greatly alleviated, and he began to part with large and copious stools, quite altered in appearance, being loaded with bile, fæculent, and lumpy. In a short time his mouth became sore; and from this and a great degree of faintness and exhaustion coming on, his pills were refused, and consequently omitted. Whether to attribute the faintness and exhaustion to the quinine, or the narcotics prescribed with it, I can scarcely decide; but the quantity of quinine taken was 60 grains (about four grains daily on the average) and the symptoms very similar to the above-noted cases. In the 33d vol. of the *Edin. Med. Journ.*, there are some remarks by Dr. Hardy on the same influence of quinine in promoting the mercurial action. It is to be remarked, in the above case, that a mercurial action, at least the specific action of mercury on the system, could not be obtained at the time mercury was exhibited, but that, a long time

after, effects the same as those produced by mercury were obtained.

I have reason to believe the sulphate of quinine employed by me was perfectly pure.—I am, sir,

Your obedient servant,

JAMES RANKING, M.D.

Ayr, N. B. March 28, 1843.

SPERMATOTZOA OBSERVED A SECOND TIME WITHIN THE OVUM.

By MARTIN BARRY, M.D. F.R.SS. L. & E.

(For the Medical Gazette.)

SEVERAL months since I communicated to the Royal Society the fact that I had observed, and shown to Professor Owen and others, spermatozoa *within* the mammiferous ovum. The ova were those of the rabbit, taken twenty-four hours *post coitum* from the Fallopian tube*.

I have this day confirmed the observation; several ova from the Fallopian tube of another of these animals, in a somewhat earlier stage, having presented spermatozoa in their interior, i. e. (as in the first observation) within the thick transparent membrane ("*zona pellucida*") brought with the ovum from the ovary.

London, 31, iii. mo. (March) 1843.

MEDICAL GAZETTE.

Friday, April 7, 1843.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

POPULATION OF ENGLAND.

THE fourth annual Report of the Registrar-General to the Secretary for the Home Department contains an immense mass of interesting and important statistical information. The portion of these documents on which we purpose making some remarks relates to the progress of population, as shewn

by the registration of births, deaths, and marriages, in the various districts of England. And we may here remark, that the kingdom has been divided into 619 districts, and these again subdivided so as to form 2184 minor portions, affording great facilities in conducting statistical inquiries.

The births and deaths are registered according to districts, and the calculations as to the increase or decrease of population made from the documents thus formed. The result of this arrangement according to districts is, that those interested may form tables of mortality, and estimate the mean duration of life in any particular situation. By these means the residents in any district or locality may accurately determine the salubrity or insalubrity of the place, and compare the results with those obtained in any other part of the kingdom. Information of this kind comes home to the feelings of every one, and will in all probability lead to beneficial results, by directing attention to the causes of disease, and the means of their removal. The value of human life, too, differs so considerably in different situations, that insurance companies and friendly societies will probably find the facts thus laid open to them of much assistance in regulating their premiums and subscriptions: nor is it easy to estimate the extent to which the information thus obtained may influence the operations of such bodies.

Much statistical information of another kind is also conveyed—such as the number of marriages, the ages of the parties, their amount of education, and various other important points. It is scarcely possible for us to do more than allude to the countless accumulation of facts which are thus brought together; but of the more interesting we select a few as specimens.

The marriages appear to have been

* See "Proceedings of the Royal Society, Dec. 8, 1842."

nearly 1 in 127; the births 1 in 32; and the deaths 1 in 45, of the whole population. This, we believe, is rather under the usual calculation as to marriage; and it is curious to observe, that the marriages in the last year were nearly 3 per cent. less than the preceding, relatively to the female population; the decrease having been most conspicuous in some of the northern divisions of the kingdom. The greatest number of marriages relatively takes place in the metropolis, a circumstance which seems to arise, in great measure, from a considerable number of persons who are usually resident in the country coming to London on the occasion of their wedding. It is thought, however, that after making due allowance for this, the number of marriages is still somewhat greater proportionally in the capital than elsewhere.

Considerable difference is observed, as might be expected, in reference to age. The proportion of women who marry under age is nearly as 3 to 1 when compared to the men, and in London is so high as $4\frac{1}{2}$ to 1. More than half the males were married between 20 and 25 years of age; and nearly the same holds good with regard to the females; but of the latter, (as may be gathered from what we have above stated), a considerable number were under 20, while comparatively few of the men were so. Yet the average age of marriage, on the great scale, is less different on the two sexes than the preceding statements might lead us to expect, being 25.5 years for the men, and 24.3 for the women.

The registration of births seems to be conducted in an unsatisfactory manner, the omissions amounting to not less than "several thousands." The proportion of births is above the average in the northern and western districts, and below it in the Welch,

eastern, and metropolitan districts. There is a slight excess of boys over girls; and this excess is greatest in the northern, and least in the southern parts of the kingdom. The greatest number of births take place in winter and spring; and it is remarkable that, during those times, the excess of males over females is also most conspicuous. But this excess does not endure more than the first twenty years of life, by which period the sexes are nearly equal, owing of course to the greater mortality of the males. More deaths appear to have occurred in 1841 than in any other year of the period, the number having exceeded that of some of the previous years by nearly 25,000.

It has long been known that the mortality is greater in cities than in the country; and the causes of this constitute a very interesting subject of inquiry, with reference more especially to their removal; and we are glad to learn that, in some of the provincial towns of England, they are undergoing rigid examination. One point clearly made out, and corresponding with what might be expected, is, that the mortality in towns increases, as a general rule, with the density of the population, owing in great measure to the comparative neglect of sewerage and purification in the poorer districts.

Another very interesting point is the mortality at different periods of life; but it is too intricate, and involves too many figures, for us to do more than allude to it. One general fact may be stated, that, under ordinary circumstances, an increase of mortality is chiefly observable among those under puberty, and among the aged; the number of deaths between 20 and 60 varying but very little.

Yet another curious point, illustrated by the marriage registers, is the state of education. The parties are required to sign their names; and it appears

that, on the average of three years, 33 men and 49 women per cent. could not do so, but merely put a *mark*. Now, taking the average ages of those who marry at 25, this test shews us the state of education from ten to twenty years ago, when it appears that, among women, very nearly one half were unable to write their own names. But there exists a great difference as to the amount of education in different parts of the kingdom. Thus, in Cumberland, only 16 in 100 signed the register with marks, while in Bedfordshire there were 52 who did so!

At the conclusion of the report a hope is expressed in which we cordially concur—namely, that the registrars will attend to the classification of fatal diseases, and that the members of the medical profession will assist, as in fact they alone can furnish correct information on the subject.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

March 28, 1843.

THE PRESIDENT IN THE CHAIR.

On two remarkably similar cases of osteo-sarcoma of the thigh bone, requiring amputation in both instances. By R. A. FROGLEY, Esq., of Hounslow, in whose practice they occurred. — Communicated by SAMUEL LANE, Esq.

THE first case is that of a female, æt. 26, who had a tumor of the thigh, which measured in its greatest diameter $35\frac{1}{2}$ inches, and reached from within an inch of the trochanters to the knee-joint. It began in the summer of 1829, with a pain in the condyle of the femur, and in May of the following year a tumor had formed of the size of the half-closed hand. It continued gradually to enlarge, without pain, or discolouration of the skin, or materially impeding the motions of the limb, till March 1843, when the limb was amputated. Owing to the close proximity of the upper part of the tumor to Poupart's ligament, it was anticipated that it might be necessary to disarticulate the bone at the hip-joint; but in the course of the operation, when the two lateral flaps had been made, the femur

was found in a healthy condition below the lesser trochanter, and it was sawn through at this joint. Mr. Lane, who assisted, commanded the blood-vessels by pressure with his fingers on the external iliac artery, so that scarcely any arterial hæmorrhage took place. What little occurred was immediately arrested by another assistant grasping the flap until as many as ten ligatures were applied. After the operation the patient caused much alarm by falling into a faint, in which she gasped as in *articulo mortis*; but she was soon restored from this condition. The stump healed favourably, and there has been no return of the morbid growth. A longitudinal section having been made of the thigh bone and tumor, it was seen to consist chiefly of a whitish, elastic, hard tissue, resembling cartilage, but rather more transparent. There was very little deposit of osseous structure in it, and the tumor appeared more connected with the periosteum than with the bone itself, which could be readily distinguished in the morbid mass, from preserving its sound condition: numerous cysts communicating with each other, and with a large central cavity, were developed in the tumor, and these contained several pints of a yellow tenacious honey-like fluid.

The second case is that of a married lady, æt. 37, who had also a tumor of the thigh. The swelling was first observed eleven years ago, as a hard lump, about the size of half a walnut, situated on the inner condyle of the femur. When seen by Mr. Frogley, five or six years after its commencement, it had not increased perceptibly in size; but in five years more it had acquired considerable magnitude, and had extended up the thigh. Finding that it made more rapid progress, so that it measured at its largest part $20\frac{1}{2}$ inches in circumference, while the thickness of the limb below was only 12 inches, she consented to undergo amputation, which was performed in August 1842, and the stump healed by the first intention. Upon making a section of the thigh-bone and tumor, it was remarked that the morbid growth, although smaller than in the preceding case, presented the identical appearances, both in position and structure, which have been described in this case. Casts, drawings, and preparations of the tumors in both patients, were exhibited.

Remarks on Gangrene of the Face, and its Treatment. By HENRY OBRE', Esq.

The author commences with some observations on the condition of the system in children, in which this disease is most liable to occur; dwelling on the ravages it produces, and its usually intractable nature. He then gives the result of his treatment of the

complaint, by applying the actual cautery to the sloughing surfaces, as recommended by some continental writers, and describes the success which he has met with. He relates two cases where he adopted the plan. In the first, the gangrene came on after typhus fever, and it proceeded rapidly to destroy a large extent of the cheek. Having tried various other applications unsuccessfully, he had recourse to the actual cautery, and immediate amendment followed, so that the edges soon healed. The appearances before and after the case were illustrated by coloured wax casts taken from the patient. In the other case, the disease was so extensive, and the child so much debilitated, that the author did not succeed in saving the patient's life; but manifest advantage was gained by the use of the cautery, so as to convince him of its beneficial influence in the treatment of the disease.

Remarks on Cancrum Oris, and Phagedæna of the Cheek, and on the Effect of the Chlorate of Potash on those Diseases.
By HENRY HUNT, M.D.

The author describes these diseases as being identical, varying only in the degree of severity—both commencing by ulceration of the mucous membrane of the cheek, or where it joins the gums, and that the external eschar is the consequence of the internal ulceration. He considers them to proceed from a cachectic state of the system; that they occur more commonly in cold and wet weather—sometimes attacking several members of the same family simultaneously, and occasionally prevailing almost like an epidemic. The author has treated them very successfully by a free exhibition of the chlorate of potash, the beneficial influence of that salt being generally apparent within forty-eight hours of its being given, that it seldom fails to arrest the progress and to effect a cure, if administered prior to the patient being very much exhausted. The quantity of the salt he has been in the habit of prescribing varies from ℥j. to ℥ij. in twelve hours, according to the age of the child. Two cases are related in corroboration of the foregoing statement.

MEETING OF THE PROFESSION IN WORCESTERSHIRE.

A HIGHLY respectable meeting of the profession of the above county was held on Tuesday last (the 4th) in the Council-Room of the Worcestershire Natural History Society, to consider the propriety of petitioning Parliament on the measures now in contemplation for regulating the medical profession.

Jonas Malden, M.D. was called to the

chair, and, after apologising for the absence of Dr. Hastings, who had been urgently called out of town, he briefly, but suitably, addressed the meeting upon the subject for which it had been convened. It was then proposed by R. J. N. Streeten, M.D., of Worcester; seconded by Anthony Martin, Esq. of Evesham; and resolved unanimously,—

That a petition be sent to both houses of Parliament on the contemplated legislation respecting the medical profession, and that the following petition to the House of Commons be adopted:—

To the Honourable the Commons of the United Kingdom of Great Britain and Ireland, in Parliament assembled.

The humble petition of the undersigned members of the medical profession, residing in the county of Worcester.

Sheweth,

That your petitioners, understanding that measures are in contemplation for reforming and regulating the profession generally, beg to represent to your Honourable House, that no reform can be effectual or permanent unless it provide for the efficiency and respectability of the whole profession, by securing uniformity of the primary qualification, tested by sufficient examination, equal right to every member to practise throughout her Majesty's dominions, and the adoption of the representative system in the formation of the councils or governing bodies.

That the supply of an adequately qualified class of general practitioners is of national importance, and that a legislative re-organization of the whole profession has become of indispensable necessity, from several causes; and, among others, from the various and incongruous modes by which medical practitioners procure admission into the profession; there being no less than sixteen different sources from which certificates of qualification may be obtained.

Your petitioners therefore pray, that your honourable house would cause inquiry to be made into the present state of the medical profession, delaying any legislative measure which might lead to the granting of new charters to the Colleges of Physicians and Surgeons until the whole subject of medical regulation and reform has been well and thoroughly investigated by a committee of your honourable house, and has undergone adequate discussion in Parliament.

And your petitioners will ever pray, &c.

Proposed by James Lewis, Esq., of Hanley; and seconded by G. M. Pritchett, Esq., of Kempsey, and resolved unanimously,—

That a similar petition be adopted for presentation to the House of Lords.

Moved by Paris Dick, M.D., of Tewkesbury; and seconded by J. H. Walsh, Esq., of Worcester, and resolved unanimously,—

That the right honourable Lord Lyttelton, Lord Lieutenant of the county, be respectfully requested to present the petition to the House of Peers.

Moved by William Cooper, M.D., of Inkberrow; and seconded by Henry B. Marsh, Esq., of Upton-on-Severn, and resolved unanimously,—

That General the Honourable H. B. Lygon be requested to present the petition to the House of Commons, and that the other members for East and West Worcestershire, the members for the City of Worcester, and for the Boroughs of Bewdley, Droitwich, Dudley, Evesham, and Kidderminster, be also requested to favour the petitioners with their support on the occasion.

Moved by W. Doughty, Esq., of Kidderminster; and seconded by David Everett, Esq., of Worcester, and resolved unanimously,—

That it appears desirable, that at the present juncture the sentiments of the members of the medical profession should be made known to the legislature; and it is therefore suggested, that meetings similar to the present, and to that which has taken place in the County of Surrey, should be called in other Counties; and it is also recommended that medical practitioners should severally, to the extent of their personal influence, endeavour to call the attention of members of both houses of Parliament to the subject of the legislative regulation of the profession.

A vote of thanks was passed to the chairman, and the petitions being signed by all present, the meeting broke up.

MEDICAL REFORM.

SIR JAMES CLARK has just published a Second Letter upon this subject. It extends to forty pages; but his views will be found embodied in the three short extracts which we subjoin, and to which we prefix headings for the convenience of our readers:—

Uniformity required in medical education.—For these and other reasons, there should, I think, be but one *prescribed* course of medical education exacted by the state; it should comprehend what is necessary for every medical practitioner; and it should be the same throughout the empire. This I consider the fundamental principle upon which a legislative enactment on the subject of Medical Education should be based. Whatever department of the profession the

medical man may choose as the field of his practice, to practise that part properly he must be acquainted with the whole. When possessed of such general knowledge of his profession, the practitioner may, by devoting his attention to one department chiefly, be fairly supposed to excel, and generally will excel, the man who practises them all. Thus one man by directing his principal attention to the investigation and treatment of diseases affecting internal organs and the general system, another by directing his chief attention to the diseases and injuries of the external organs and the operations and mechanical appliances required for their cure, may each attain, in their respective departments, a degree of perfection which cannot be expected of him whose attention is divided among the whole range of human infirmities and accidents. Hence there will always be Physicians and Surgeons who, in addition to their individual practice, will be consulted by the General Practitioner in all dangerous and obscure diseases; and every honourable inducement should be held out to encourage men to qualify themselves for such responsible positions by a higher preliminary education, and a more extended course of professional instruction, than could be laid down as the rule for all medical practitioners. But, as Dr. Thomson has justly remarked, “It is in the proper education of the whole body of the members of the medical profession, and in the experience which particular individuals may acquire by extensive private practice, or by attendance in dispensaries or hospitals, that the public have their best, and indeed their only securities for an adequate supply of intelligent and experienced Consulting Practitioners. The Legislature, therefore, will have performed its duty when it shall have taken care that no one can be licensed to enter on the practice of medicine without such preparation as a thorough preliminary and professional education can afford. Beyond the requirements necessary to obtain a license which should entitle the possessor to practise any and every branch of his profession—to qualify, in short, for a General Practitioner—the Legislature need not, perhaps ought not, to interfere with Medical Education or Medical Degrees. The regulations respecting honorary Degrees in Medicine may be safely left to the Universities and Medical Colleges.

Although medical education in this country is much superior to what it was, even a quarter of a century ago, it is still defective in all classes. The education of the Physician is defective, inasmuch as he is not generally instructed in all the departments of his profession. That of the Surgeon is still more limited. He has, in truth, been

hitherto educated almost exclusively in surgery, whilst his practice is as much in medical as in surgical diseases : his knowledge of medicine is therefore generally acquired during the first years of his practice ; and, moreover, the confined range of his medical education is unfavourable to his ever becoming a good Physician. The education of the General Practitioner, although much superior to what it was, has not by any means kept pace with the increase of his professional responsibilities. It is defective in several ways, but more especially in its preliminary or general part—in those departments of science a knowledge of which is necessary to prepare him for entering on his more strictly professional studies. To bring the education of the General Practitioner up to the standard of his responsibilities it is that a legislative enactment is required.

Necessity of having an Educational Board independent of the Medical Corporations.—When the standard of medical education has been raised to what it ought to be, the next point for decision will be the formation of a body to whom is to be delegated the power of carrying out the principles of education laid down by the government. That power should, in my humble opinion, be intrusted only to an independent body, unconnected with the educating institutions on the one hand, and the medical corporations on the other ; a body responsible to the government for its acts, having no collateral interests to divert its attention from carrying out in the fullest manner the principles embodied in the legislative enactment. But I have stated my views on this subject in my former letter, and further reflection has only tended to confirm my opinion,—that this important trust should be vested in a body in each division of the kingdom, appointed by Government, for the exclusive purpose of regulating the course of education, preliminary and professional, and of testing candidates for licenses to practise.

Unless the regulation of medical education is intrusted to such a body, it will be in vain to expect well-educated medical men. The subject of education must be taken up as a whole, and directed upon a well-devised system, otherwise it can never be successful. It has been because the regulations respecting the education of medical men have been intrusted chiefly to the Medical Corporations that the preliminary education has been so totally neglected. Such bodies are not qualified to test candidates on their scientific acquirements. It is not their province, and in no other country, I believe, is such a duty intrusted to them. If the Colleges of Physicians and Surgeons are to have any share in examining candidates, it should be

restricted entirely to testing their practical knowledge. The selection of a proper body for this purpose, for regulating the education and testing the qualifications of medical men, appears to me, in point of importance, and in the accomplishment of a sound reform of the medical profession, second only to the establishment of a good preliminary and medical education to be required of every member of the profession as a condition of his receiving a license to practise.

Necessity of Separating Pharmacy from Medicine.—In thus advocating a liberal education for the General Practitioners, as the only means of insuring their respectability as a body, and giving them a status in their profession, it must be evident to themselves that so desirable a change in their position cannot be effected until the dispensing of medicines ceases to be a part of their duty—until the practice of Pharmacy is separated from that of Medicine. In towns the separation may be effected without difficulty. In Edinburgh it may be said to be already accomplished. It is true that in villages and country districts the Practitioner would require to keep such medicines as were necessary for immediate use, more especially in the treatment of acute diseases. In such cases, however, the medicines ought not to form a separate charge, but be included in that for attendance, being considered in the same light as surgical instruments. But until the practice of Pharmacy is separated generally from that of Medicine, General Practitioners cannot attain that position in their profession, nor hold that station in society, which they ought. The influence which such an arrangement in the practice of Medicine would exercise on the position of Medical Practitioners generally, must be sufficiently obvious to every one who gives the subject a little consideration ; but the far greater benefits which the public would ultimately reap from it can only be known to those who are acquainted with the present state of medical practice in this country.

Difficulties will, no doubt, present themselves to the establishment of a uniform scheme of medical education ; but these difficulties are really less formidable than they at first sight appear to be.

The present Medical Corporations and the English Universities may oppose such a measure. The opposition of either ought to have little weight, if it can be shown to be unreasonable and opposed to the public weal ; and assuredly whatever is opposed to the improvement of Medical Education and to the character and respectability of the great body of Medical Practitioners is so.

FATAL EFFECTS OF HOMŒOPATHY.

To the Editor of the Medical Gazette.

SIR,

ANOTHER victim is added to the lengthening list of homœopathic deaths. The obituary of to-day announces the decease of a lady of rank, a believer and follower of homœopathy.

In a former communication to you touching the melancholy death of another lady of rank, I elicited two charming productions in the shape of a vindication of the homœopathic treatment, and which pretty clearly verified the adage, which I must only hint at—it was a quarrel between two culinary friends as to which was the blackest. Now I wish to reverse the matter, and ask for the doctor's version of the case before I send you my account of it; and as I love the science of medicine, *especially that of homœopathy*. I would beg Dr. C——, the attendant on the late Lady L—— D——, to give us the particulars of the failure of the remedies used; *known as certain preventives of the contagion of scarlatina*, and from what circumstances a *fatal* instead of a *favourable* issue resulted. I have no doubt but that it will be greatly conducive to extending the belief in, and practice of homœopathy, to know if in this case the patient was lost from *broth! brandy!!* or *belladonna!!!* It is to be hoped that Dr. H. D—— was also in attendance, and will favour the medical men “who will take the trouble of calling on him” with his statement of the case, as between their *conflicting* accounts the truth may be rendered visible to people of plain common sense.

Dr. Curie, in his letter (see MEDICAL GAZETTE, 3d February, 1843), alludes to his great patron, thus: “Like a noble earl well known for the interest he takes in medical science, who has not thought it beneath him, in order to complete his general education, to take his place upon the benches of a surgical class.” Now in these days our aristocracy are doubtless very learned and scientific men, but I would suggest that the ability of this noble earl must be more than *gigantic*, when a single course of lectures shall enable him to judge, and lead others into the belief, of a system, which is pronounced by men whose years of experience greatly outnumber those of the noble earl's age, to be based on a foundation of absurdities, and dangerous in its practice. May we ask, with that deference which becomes us in approaching a person of such transcendent powers, what his feelings are, if he deign to reflect on the awful results of his recommendation.—I am, sir,

Your obedient servant,

M.D.

ON
THE PHOSPHATES IN POTATOES.

To the Editor of the Medical Gazette.

SIR,

IN Dr. Golding Bird's lecture, contained in the last number of the LONDON MEDICAL GAZETTE, is a table showing the “proportion of phosphates in articles of diet.” In this table Dr. Bird states, on the authority of Liebig, that one ounce of potatoes contains 23·56 grains of phosphates; and he goes on to show, that if a person take three ounces of potatoes at a meal, he consumes 94·24 grains of phosphates.

Now, according to Cocker, if one ounce of potatoes contain 23·56 grains of phosphates, three ounces must contain 70·68, not 94·24 grains.

But I should be glad to be informed in what part of Liebig's writings does this distinguished chemist state that an ounce of potatoes contains 23·56 grains of phosphates? At page 285 of his Animal Chemistry he quotes the following analyses of Boussingault and Boeckmann:—

<i>Potatoes.</i>			
	Boussingault.	Boeckmann.	
Water	72·2	73·2	
Dry matter . .	27·8	26·8	
	100·0	100·0	

And in the same page it is also stated, that 100 parts of potatoes [*thus dried*] contain, according to Boussingault 5·0, according to Boeckmann 4·915 per cent. of ashes. Consequently, in 100 parts of undried potatoes, there would be, according to Boussingault, 1·39 parts of ashes; and assuming these to consist entirely of phosphates (which they do not), one ounce Troy of potatoes would contain 6·672 grains of phosphates, instead of 23·56 grains as stated by Dr. Bird; and, therefore, if a man took at a meal three ounces of potatoes, he would consume 20·016 grains, not 94·24 grains, of phosphates.

In these calculations I have followed Boussingault's analysis, as quoted by Liebig, since it is the most favourable to Dr. Bird's statement. But his later analysis* is more unfavourable, since it shows that one ounce of potatoes really yields only 4·6272 grains of ashes.—I am, sir,

Your obedient servant,

A CONSTANT READER.

* Mémoires de l'Académie Royale des Sciences, t. xviii. 1842.

FŒTAL CIRCULATION.

To the Editor of the Medical Gazette.

SIR,

SINCE the appearance of the last number of the GAZETTE, I have received a note from Dr. Carpenter, of Bristol, directing my attention to the circumstance that I had committed an error in my paper on the Foetal Circulation, published in your last number, in ascribing to *him* the paternity of the notion which regards the red particles of the blood in the light of glandular agents destined to convert the simpler or least organized elements which enter, from various sources, the current of the circulation, into its higher and more animalized principles. Some time had elapsed since I had read his admirable article on the Physiology of Cells, published in Forbes's Foreign Review for January 1843. On again referring to the same source, I find that Dr. Carpenter contends against, rather than advocates, this view, which, on the contrary, is entertained by Wagner, Henlé, and Wharton Jones.

He maintains the somewhat modified doctrine, that since the blood of invertebrata is altogether destitute of *coloured* corpuscles, while it abounds in the *colourless*, united to the fact, that, like the changes which are perpetually being kept up in the blood of the vertebrate animal, the albuminous principles in their blood must be continually undergoing similar transformations into the more elaborate fibrinous products, this mysterious catalysis is a duty which must devolve rather upon the *colourless* than the *coloured* corpuscles of the blood. I think now that I have rectified the mistake, and placed the pleasing fabric of this sweet-sounding theory upon the merited eminence of a "cloudless vantage ground:" those who desire further information upon the subject I must refer to the valuable and superior paper of Dr. Carpenter.—I am, sir,

Your obedient servant,

THOMAS WILLIAMS.

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE XXIII.

*Protracted and difficult labours, from
rigidity and premature rupture of the
fœtal membranes; over-distension of the
uterus; and unusual size and presentation
of the head of the child.*

VENESECTION, as recommended so strongly by Mauriceau, is undoubtedly the most important remedy which can be employed in cases of protracted labour from rigidity of the os uteri and other soft parts, especially where there is fever with determination of blood to the head. But it is not generally necessary to take away more than twelve or fourteen ounces of blood from the arm, or twenty in very robust plethoric persons, and I have seen no cases in which the abstraction of forty or fifty ounces at a time was required, or would have been justifiable. In America, women have been bled to this, or to a still greater amount, to promote general relaxation of the system, and of the parts. But, like other powerful remedies, as Dr. Merriman observes, "this has sometimes been carried to excess, so as to be injurious to the patient during parturition, and rendering her recovery tedious, if not doubtful." A woman with rigid os uteri during labour does not require the same quantity of blood to be taken away which it would be necessary to remove if she were labouring under pneumonia or peritonitis. The results of my experience on this point are very different from those of Dr. Hamilton, who says,

"hitherto, in a very large proportion of the cases of protraction from this cause, he has found copious blood-letting rapidly promote the dilatation. By copious blood-letting he means, abstracting as much blood by one venesection as he should direct in a patient of a similar constitution, if she were labouring under an acute inflammatory disease." He admits, however, that "in cases of relaxed debilitated women, with *toughness* of the os uteri, venesection cannot be ventured upon, and it becomes necessary to administer an opiate enema. The author had recourse to this practice, he must confess, with great reluctance, having seen many cases where the administration of opiates had been prejudicial. But he can now say that, under proper management, the practice is safe. The utility and safety of the practice are mainly influenced by the time at which it is adopted. If strong and frequent pains, continued for six or eight hours, do not decidedly promote the dilatation, the opiate enema should be had recourse to, and it will seldom disappoint the expectation of the practitioner. But if the first stage, with strong and frequent pains, be allowed to go on for twelve hours or upwards, without having completed the dilatation of the os uteri, there is the risk that the opiate will so far interfere with the progress of the labour that instrumental delivery shall become necessary." "In some instances," says Dr. Collins, "especially with first children, the mouth of the womb continues rigid and hot, with little tendency to yield under uterine action, accompanied not unfrequently by considerable irritation. In such, bleeding to the extent of ten or twelve ounces, and keeping the patient under the influence of slight doses of tartar emetic, to which a small quantity of opium should be added, will be found to promote relaxation, and thus be productive of the best effects." Spontaneous vomiting is often followed by relaxation of the os uteri, but I have never ventured to prescribe an emetic to any woman in labour.

Dr. Lowder says that he seldom found benefit from their exhibition, though he has frequently seen them used. The warm bath was employed in America, but excessive hæmorrhage so often followed it, that the practice was abandoned. Dr. Merriman states that he has seen good effects produced from the warm or tepid hip-bath, in relaxing the soft parts. "Upon the same principle of inducing relaxation and consequent dilatation of the os uteri, he says clysters of tobacco were recommended in America: but the alarming symptoms which followed in the single case where tobacco was thus employed, will I trust prevent a repetition of this experiment."

In some cases, after the labour has continued many hours, the os uteri is so thick, hard, smooth, and polished, and so little dilated, that you might be induced to believe that the head would never pass, but it is astonishing how it will yield in time if you have patience, and employ the proper measures to prevent exhaustion and fever. These means will not, however, invariably succeed, and artificial delivery sometimes becomes imperative, and from all that has fallen under my observation I am convinced that there is far less danger from premature interference, than from delaying too long to deliver artificially. In the eleventh volume of the Medico-Chirurgical Transactions, Mr. P. N. Scott, of Norwich, one of the most judicious and experienced practitioners now in Britain, has recorded the following very remarkable case of extreme rigidity of the os uteri, in which the separation of the inferior segment of the uterus took place during labour, and the patient recovered. "On Sunday, the 29th of October, at seven o'clock in the evening, I was requested by Mr. Keymer, a respectable surgeon of this city, to visit Mrs. Hall, a married woman, aged 36, who was in labour of her first child. He stated to me that he had been in attendance for sixteen hours, that labour had commenced about six o'clock on the Saturday evening, when he first saw her, and that though the liquor amnii (as he was informed by the nurse), had escaped some hours previous to his first visit, there had been but little progress made towards delivery. Mr. Keymer is a gentleman of very extensive experience, having been above fifty years in large practice, particularly in this branch of the profession, but he assured me that he had never seen a case in which the sufferings of the patient were so extreme, and in which the os uteri was so tense and rigid. On seeing the patient, I found that her sufferings continued unabated, that the os uteri was not dilated to more than the size of a half-crown piece, and that it was principally of a thick, unyielding, but, at a small portion of its

extent, of a somewhat spongy texture. As Mrs. Hall was of a very thin, spare, delicate habit, I thought it improper to bleed her, and therefore recommended warm fomentations, and other means to allay irritation. The following morning, at eleven o'clock, I again visited her with Mr. Keymer; she had passed a restless night, distressed with most violent and constant pains, continually exclaiming that she was certain she would burst. I found her in a most alarming state, and she appeared to be rapidly sinking: she with difficulty told me, that two hours before, during a most severe pain, she felt something snap, and to use her own words, 'the web of her body had given way;' the noise of which one of her attendants declared she heard; the pains had then suddenly ceased, attended with a discharge of blood, fainting, cold sweats, feeble pulse, and a vomiting of a brownish fluid. On introducing my hand under the bed-clothes, I found there had been a very considerable hæmorrhage, and among the coagula I discovered a substance which I put aside for future examination. At this time I found the head of the child so low as to enable me to accomplish delivery speedily with the vectis. The child was living, and the placenta was expelled without any difficulty. After waiting some time, by the use of light cordials the patient appeared to revive, but there was a singular fulness and tension of the abdomen, such as I had never before witnessed. It appeared to me to be a hopeless case, and I left the patient, fearing she could not long survive. On the Tuesday morning her abdomen was swelled to an enormous degree, much larger than previous to her delivery, and for ten days it remained very tense and tender: the pulse was at the same time exceedingly rapid and feeble, skin hot, and tongue furred. I drew off between three and four pints of urine in a very foetid and acrimonious state, and had occasion to repeat this operation three or four times in as many days. In a week the bowels required large doses of calomel, Epsom salts, senna, &c. &c. to relieve them, and for a month the patient was feverish, and excessively weak and languid. During this time several large coagula were expelled, and the body regained its natural size. She was much emaciated, but by the use of light tonics and nutritious diet she gradually recovered her strength. Her health is now much re-established, but she has always suffered considerable inconvenience from a slight prolapsus uteri, which still continues. There is very considerable tenderness in the pudenda, and at the last examination per vaginam, which was about three weeks after the delivery, I found a continuous cavity, without any distinction between vagina and uterus. The catamenia

appeared about five weeks ago; they were preceded by pain in the back, and continued in very small quantity for two days. The child is in good health, and the mother has a plentiful secretion of milk. The appearance presented by the os uteri, and an irregular part of the cervix surrounding it, has been represented in *this* coloured engraving [shewing it] which precedes the paper. I had an opportunity some years ago of seeing the preparation of the parts at the Middlesex Hospital, in the collection of Dr. Merriman, which passed into the possession of Dr. Hugh Ley, and since his death into that of Dr. Bull. I could not obtain permission to remove it from the spirits to ascertain if the Nabothian glands and pennisform rugæ were visible, but the whole history of the case, and the appearance of the preparation, leave no doubt that the os uteri and cervix had been torn away from the body of the uterus. A great many anatomists and surgeons who examined the part in the recent state formed this opinion. Mr. Scott concludes this communication with the following explanation of the manner in which the accident occurred. "It has appeared to me, as Dr. Merriman suggested, that the head of the child passed through the superior aperture of the pelvis, carrying the uterus before it with the os uteri very little dilated, and that in this way the dilatation of the uterus was prevented by the head pressing it firmly against the sides of the pelvis, so as to prevent the action of the uterus from being exerted on the cervix. The great force of the uterus acting on the body of the child might thus produce the separation of the circular portion exhibited." I saw a case in consultation with Mr. Owen, of Holborn Bars, where the os uteri was thick, hard, smooth, and so little dilated, and pressed so close to the outlet of the pelvis after labour had continued for thirty hours with great severity, that it seemed probable an accident similar to that described would take place, but the labour was at last safely effected. After venesection, an opiate enema, and artificial dilatation, had been employed.

Oblique position of the os uteri has been enumerated by Dr. Denman among the causes of difficult labour depending on rigidity of the parts to be dilated, and Daventer erroneously attributed nearly all difficult labours to obliquities of the uterus. Where great relaxation of the abdominal parietes exists, the fundus uteri sometimes falls forward, and the os uteri is consequently thrown upward and backward in an unusual degree, but this cannot be regarded as a common cause of difficult labour, and where it occurs it is readily relieved by applying a bandage firmly around the body, and by

keeping the patient during the first stage of labour upon the back with the shoulders slightly depressed. Daventer, Baudelocque, and Desormeaux, have all attributed an undue degree of importance to obliquities of the uterus, and have recommended passing the fingers, or even the whole hand, into the vagina to push the head of the child above the brim of the pelvis, and also the lower part of the uterus, and with the extremities of the fingers to drag forward the anterior lip of the os uteri to the centre of the pelvis, and to keep it there until complete dilatation has taken place. This is one of the numerous and dangerous manoeuvres described by writers, which ought never to be thought of. "Cases have been recorded," says Dr. Denman, "in which it was said that the os uteri was perfectly closed, and in which it has not only been proposed to make an artificial opening, instead of the closed natural one, but the operation has actually been performed. I do not know that I should be justified in saying that such cases have never occurred in my practice, but I am persuaded that there has been an error in this account, and that what has been called a perfect closure of the os uteri has not been such, but that we have been unable to discover it by reason of its obliquity."

Dr. Merriman is of opinion that the cases of difficult labour from the os uteri being projected above the symphysis pubis, described by Daventer and other writers, were instances of retroversion of the uterus at the full period. I have met with no cases tending to confirm or refute this opinion. Sometimes the os uteri descends with the head to the outlet of the pelvis, or actually passes through it at the commencement of labour: where this happens, the patient should be placed upon the back, with the pelvis elevated and the shoulders depressed, and the prolapsed uterus returned to its natural situation by long-continued gentle pressure with the expanded fingers. In some cases the anterior wall of the vagina and neck of the bladder are pushed down even through the external parts during labour, before the presenting part, and sometimes the posterior wall. In one case the latter was mistaken for the foetal membranes, and an unsuccessful attempt was made to perforate with the finger the back part of the vagina. Where this accident occurs the protruded part of the vagina and bladder should be pressed up and supported by the fingers during the pains, that the head of the child may escape. Dr. Merriman relates a case in which the bladder distended with urine filled up the anterior part of the vagina, and was punctured and afterwards sloughed. The practitioner supposed that it was the child's head enlarged by hydrocephalus.

3. *Of protracted and difficult labours from rigidity of the foetal membranes—their premature rupture—imperfect discharge of the liquor amnii—over distension of the uterus by dropsy of the amnion and a plurality of children.*

The membranes not unfrequently burst spontaneously, and the liquor amnii begins to escape before the commencement of the labour pains and the dilatation of the os uteri. One, two, or three days, or only a few hours, may elapse after the water begins to flow and uterine action occurs. The nature of the presentation should be ascertained as soon as possible by an internal examination, in all cases of premature rupture of the membranes.

The early rupture of the membranes is almost a diagnostic sign of preternatural presentations. The whole liquor amnii may be quickly discharged, or if the opening in the membranes be small, and at a distance from the cervix uteri, or the head of the child lies over the aperture, it may escape in small quantities at a time, or it may ooze out slowly, and keep the patient during a long period in a very uncomfortable state. When active uterine contractions take place, whether it be a first or subsequent labour, the process often goes on as safely and expeditiously as if nothing unusual had occurred, and no interference is necessary or proper. It is only in cases of labour protracted by feeble uterine action, from imperfect discharge of the liquor amnii, or, as it has been called, dribbling of the waters, that any thing is required to be done, and then the membranes should be freely torn open, and the head of the child held up or pressed towards the sacrum between the pains, and the os uteri, if not rigid, very gently dilated with the fingers. Unusual rigidity or thickness of the foetal membranes, with or without an excessive quantity of liquor amnii, is a much more common cause of protracted labour than their premature rupture, and their artificial rupture is often followed by strong and regular contractions, and the safe and speedy termination of the labour. If the perineum and os uteri are rigid, and the head is high up, and it is the first child, it is seldom necessary to have recourse to rupturing the membranes before the first stage of labour is nearly or fully completed. When the first stage is far advanced, the parts yielding, yet the pains are feeble and ineffective for several hours, then you may rupture the membranes. Where there is a great quantity of liquor amnii, or the uterus is over distended by twins, it has not the power to contract upon its contents with sufficient force to rupture the membranes, and it may become completely exhausted if this is not done artificially. The uterus, as Smellie states, cannot come

in contact with the body of the child, and press down the head, until the membranes are pushed a considerable way before it into the vagina, nor even then until they are broke. Where there is a considerable quantity of fluid between the head and membranes, and the pains are sufficiently strong to render them tense, there is usually no difficulty in perforating them with the point of the finger sharply forced against them; but where the pains are feeble, and the membranes are in contact with the head, very great difficulty is often experienced in opening them. The best and safest method is to pass the nail of the fore-finger backward and forward over the membranes like a saw, till the liquor amnii is felt escaping. I have never found it necessary to use a probe, or any other instrument than the finger, for this purpose.

4. *Of protracted and difficult labours from shortness of the umbilical cord, in consequence of being twisted once or several times around the neck and trunk of the child.*

Sometimes the umbilical cord is so short, without surrounding the neck of the child, that it is torn during the expulsion of the trunk and lower extremities, or it is necessary to tie and divide it before they can be extracted. Much more frequently the cord is twisted once or oftener around the neck, and during both the first and second stages of labour the head is in consequence not only retracted upon the declension of every pain, but during the pains it is not pushed forward with the usual force, and the labour is protracted. In some cases the head is held up so high by this twisting of the cord around the neck that the nature of the presentation cannot be positively ascertained till the first stage of labour is nearly completed. You may suspect it to be an arm presentation, because no part of the foetus can be touched when the os uteri is fully dilated; and yet, when the hand is introduced to turn, and the membranes are ruptured, the head presents, and is prevented from descending in the ordinary manner from the shortness of the cord. In the second stage of labour, when the head is in the cavity or pressing against the parts at the outlet of the pelvis, you may suspect that the cord surrounds the neck, by the head receding in an extraordinary manner after each pain goes off. There is no rigidity of the parts, nothing unusual about the size and position of the head, no deficiency of uterine contractions, yet the head does not pass for many hours; not, indeed, till your patience and the woman's strength are both very nearly exhausted. You may be certain that this is the cause of the delay by passing up two fingers, or the whole hand as high as possible between the

symphysis pubis and head, and feeling the cord surrounding the neck. If it pulsates strongly I entreat you to have patience, to leave the case to nature if immediate delivery is not necessary on some other ground, and to abstain from exhibiting ergot of rye or applying the forceps. But if the pulsations were becoming gradually feebler, and you had proofs of the foetal circulation being interrupted, and the labour were greatly protracted, the best practice certainly would be immediately to deliver with the forceps. In a case of tedious labour, which I lately saw in consultation with Mr. Russel, of Broad Street, I declined at first employing the forceps, because the cord was around the neck and was pulsating vigorously, and the mother was not exhausted; but after some hours the pulsations in the cord had become extremely weak, and the child would probably have been destroyed in a short time had we not interfered. The blades of the forceps were easily applied, and the child was soon extracted alive and uninjured.

The operation of turning was sometimes had recourse to by Smellie in these cases.

"In June 1751," he says, "I was called by a midwife to a woman who had been many hours in labour, and found, that after the discharge of the waters, the head was forced low down by every pain, but afterwards drawn up again. I was likewise informed, that formerly she used to have large children and quick labours. Encouraged by this information, I tried to turn the child, but was prevented by the strong contraction of the uterus; but in making this trial, and raising the head, I not only found the funis surrounding the neck, but likewise the uterus contracted before the shoulders. This last I dilated with my fingers as much as possible, then withdrawing my hand, applied the forceps and delivered the child, which had been dead for some days. The funis was three times round the neck, being much tumified and of a livid colour." Smellie made two capital mistakes in the treatment of this case; the first was in attempting to deliver by turning the child, which ought never to be done under similar circumstances, and which I hope the uterine contractions will also prevent you from carrying into effect should you make the attempt. The next practical mistake was in delivering with the forceps, when he knew, or ought to have known, that the child was dead.

5. *Of protracted and difficult labours from unusual size and ossification of the head of the child. Hydrocephalus—the forehead situated under the arch of the pubes—presentation of the face—one of the arms with the head—death of the child, and the distension of its abdomen with air or fluid.*

If the pelvis is not above the average size, and the head is unusually large and hard, it

will pass through the apertures with difficulty, or be arrested in them. The progress and termination of these cases is similar to those in which the pelvis is small or distorted, and the head does not exceed the ordinary size. If the disproportion between the head and pelvis is inconsiderable, the labour is protracted, but if time is given, and no improper treatment be employed, it is at last completed without artificial assistance, and the child's life is preserved. But where the head is much too large to pass, it becomes arrested and impacted in the brim; the bones are gradually compressed, so as to ride over one another between the pains, and it becomes swollen and elongated in a remarkable manner, where the head has been allowed to remain long strongly compressed either in the brim, cavity, or outlet of the pelvis; the child is usually destroyed by the injury inflicted on the brain, and the soft parts of the mother suffer from the long-continued pressure. The symptoms which here indicate the necessity for artificial assistance have already been fully described, and the safety both of the mother and child will generally, I am satisfied, be best secured by interposing as soon as it is evident that the natural powers are insufficient for the expulsion of the head.

Hydrocephalus in the child is not a common cause of protracted labour; but the diagnosis is very difficult, and if the nature of the obstruction be not early ascertained the result has generally been unfortunate; the os uteri dilates or is dilatable; but the head, if much distended with fluid, cannot enter or pass through the brim of the pelvis, and exhaustion or rupture of the uterus takes place. Where the affection is in a slighter degree, or if the pelvis be very large, the head is expelled by the pains undiminished. "I have known," says Dr. Merriman, "one hydrocephalic foetus pass entire, the circumference of whose head was seventeen inches; another passed alive, and lived an hour, whose head measured in circumference twenty-two inches; both the above labours were long and painful." Where the cause of the difficulty is clearly ascertained, by feeling the bones of the foetal head widely separated from one another, and a sense of fluctuation is also perceived, and where the os uteri is dilatable, and the pains have continued strong for some hours, and the head has not entered the brim, the perforator should be employed without loss of time. The following cases which have come under my observation will convince you that congenital hydrocephalus is detected with great difficulty during labour, and that it is often followed by the most fatal consequences. Every case of this kind which I have seen has terminated fatally, and in the greater number of them the cause of the difficulty was not ascertained till it was too late.

In 1834, I was called to a woman in

Warwick Street, who had been in labour nearly 60 hours. It was the first child. The head had not entered the brim, and it had not been discovered that the head was enormously distended with fluid. The delivery was easily effected by the perforator and crotchet; but inflammation of the uterus took place, which proved fatal in a few days. On the 14th of July, 1829, the late Dr. John Prout called me to see a woman, æt. 31, residing at No. 6, Draper's Place, Euston Square. She had been long in labour with her first child, and the presentation could not be positively determined. After the escape of an immense quantity of liquor amnii, and the complete dilatation of the os uteri, the presenting part remained entirely above the brim of the pelvis. It was not till I introduced the hand into the uterus, to deliver by turning, that I knew with certainty that the head presented, and that it was distended with fluid. Instead of turning, the hand was immediately withdrawn on the nature of the difficulty being ascertained, and the perforator employed, when several pints of a bloody fluid gushed out. The head was readily extracted, but she had a violent fit of cold shivering immediately after, and had nearly died from exhaustion. She was ultimately destroyed by uterine phlebitis and gangrene of the lungs. On the 12th of March, 1828, I saw another case of hydrocephalus in the fœtus with dropsy of the amnion, where the nature of the difficulty was not ascertained in time to be of any use to the patient, who was left too long in labour, and afterwards died from inflammation of the muscular structure of the uterus. But the two most unfortunate cases of difficult labour from hydrocephalus that I have ever seen occurred last summer, and within a week of one another. Their histories are the following:—

A woman near the full period, residing at No. 9, Castle Street, St. Martin's Lane, was seized with slight labour-pains on Saturday, June 18, 1842. The liquor amnii soon after escaped. The pains continued during the 19th and 20th at long irregular intervals, and had little effect on the os uteri. Early on the morning of Tuesday, the 21st, they were stronger and more frequent, and the midwife thought the labour would soon be finished. Suddenly a violent pain, like spasm, was experienced in the epigastric region, and soon after, sickness, faintness, hurried breathing, and coldness of the extremities, took place. Mr. Tucker was called to her about two hours after the occurrence of these symptoms, and found the placenta filling the os uteri, which was considerably dilated, and some hæmorrhage going on. I saw her not long after, and thought she would probably die before the delivery could be completed. The hand passed readily into the uterus, and, there

being no pain, came in contact with what seemed at first the bodies of two children. It was passed on to the fundus, where there was a foot felt. I grasped this, and, without the slightest exertion, brought it down and extracted the trunk and extremities of the child, but the head would not follow. I perforated the back part of the head with the scissors, when there escaped a very large quantity of fluid, and it was not till this began to flow that I properly understood the cause of the difficulty. With the crotchet passed into the opening, the head was easily drawn through the pelvis, and the placenta being loose was soon removed. Little hæmorrhage took place, and for twenty-four hours the symptoms were so favourable that it appeared she might recover. The sickness, however, never subsided, and she died suddenly forty-eight hours after being delivered. I examined the body the following day with Mr. Tucker, and we found all the coats of the uterus torn from the fundus to the orifice on the anterior part. (The uterus is in my possession, and you shall have an opportunity of seeing it.) There were 3ij. of blood in the peritoneum. The bones of the head were at least twice the natural size, the ossification, particularly of the parietal bones, having kept pace with the distension of the head from the fluid. The skull has been dried, and you see it is nearly as large as the head of an adult.

Mrs. G——, æt. 30, 96, Drummond Street, Euston Square. Being at the full period of pregnancy, the liquor amnii began to escape at 6 P.M. 22d June, 1842. Labour pains commenced at 1 A.M. of the 23d, and Mr. Kennedy, of Tavistock Square, saw her at 3 A.M. The pains were feeble till 11, and then for several hours after they became more active and frequent. At 3 P.M. a small loop of the funis, along with the head, was felt at the brim of the pelvis. The pains gradually ceased after 3, and she complained of cramps about the stomach. At 6, there was no dangerous symptom; but at 8, violent pain was felt at the fundus uteri. At 10 P.M. I first saw her with Mr. Kennedy; she was then sitting up in bed, supported by pillows, the breathing hurried and pulse feeble, with sickness and vomiting. She complained of excruciating pain in the upper part of the uterus, which she could not bear to be touched, and which felt remarkably hard and irregular. Slight hæmorrhage from the uterus; the funis still felt, but the presenting part had receded beyond the reach of the finger. I passed the hand into the uterus and felt the placenta adhering to the posterior wall, but could feel no part of the child. So violent was the pain produced by the hand, that I withdrew it without making any attempt to pass it through the opening in the uterus to extract the child. A large opiate was given,

and she fell asleep for a short time. Feeling anxious that she should not die undelivered, we resolved to make an attempt to extract the child. I again passed the hand into the uterus, carried it forward through a great rent in the fundus, when it came immediately in contact with one of the feet, which I seized and brought back into the uterus. I had little difficulty in extracting the trunk and extremities of the child, but the head would not follow, though great force was employed, till perforated behind one of the ears, and then several pints of fluid escaped. Abdominal inflammation followed, the acute symptoms of which yielded to treatment; but fifteen days after delivery fæculent matter began to pass by the vagina, and the whole continued to escape through the vagina for thirteen days after, when she died. The omentum and all the parts around the uterus were glued together. The lower part of the ilium adhered firmly to the fundus uteri. On separating the ilium, a large irregular opening was seen in the uterus, the edges of which were in a black sloughing state. The ilium was perforated in the part corresponding with the rent in the uterus, and through this opening the fæculent matter had passed from the ilium, through the cavity of the uterus, into the vagina. Had the cause of the difficulty been ascertained sufficiently early in this and the four preceding fatal cases of hydrocephalus in the foetus, it is impossible to doubt that several of them, if not all, would have ended favourably.

In a case of difficult labour from hydrocephalic foetus, recorded by Perfect, the woman died in two hours after being delivered. The head was twenty-four inches in circumference.

Smellie has related four cases of hydrocephalus, one of which occurred in 1747, and he states that after the orifice of the uterus was largely dilated, the head continued long high up at the brim, and felt in such an uncommon manner that he was for some time uncertain whether it was the head or breech, but the waters being discharged it was pushed a little lower down; then he felt the hairy scalp, and perceived the head was dropsical from the looseness of the bones, and the great distance between them. The head was expelled without artificial help. Another case occurred in 1753. It was the first child. The membranes and waters opened the os uteri in a very slow manner, and when they came down to the middle of the vagina, felt as if there had been one set of membranes within another, though the internal seemed to be much thicker than the external. But before the os uteri was fully opened, the membranes broke, and then I discovered the other was the hairy scalp,

pushed down by water contained in the skull. This the pains forced down lower and lower, so that the os internum being fully opened, it stretched the vagina and the os externum in the same manner as they are commonly dilated by the membranes and waters of the secundines; and he says, I felt the bones of the skull loose and riding one over another. The head was expelled without assistance, but a good deal of force was required to extract the body and shoulders, because the abdomen was swollen. The child had been dead ten days. These cases prove that the diagnosis is sometimes most difficult in protracted labour from an hydrocephalic state of the foetus, and that it has often terminated fatally. I have related these and the following cases with the view of rendering you cautious how you employ ergot of rye, or any other means, to excite strong uterine contractions before the presenting part has been clearly ascertained.

Smellie mentions another case in which flooding took place before delivery, and all his efforts to extract the head after turning were useless in consequence of hydrocephalus. He exerted great force, and continued to increase it till he found the neck and mouth to give way. A curved crotchet was then passed up along the child's head to the upper and convex part of the forehead, and, on pulling forcibly, the bones of the skull collapsed, and a quantity of water escaped. The head was about a third larger than common, and the woman died 18 or 20 days after. The delivery would have been more easily effected by perforating the back part of the head, and then extracting it with the crotchet, which he did in another case. In the 4th vol. of the Medico-Chirurgical Transactions, Sir C. Bell relates a case of hydrocephalus in which the uterus was ruptured. Dr. Ramsbotham relates three cases, two of which terminated fatally.

Ascites in the foetus is a still more rare disease than hydrocephalus, and it may prevent the body of the child following the head through the pelvis. The same effect is produced by distension of the abdomen with air where the foetus is dead, and where the kidneys and bladder are distended with urine in consequence of the urethra and ureters being impervious. In all these cases, where any difficulty arises in extracting the trunk of the child, the perforator should be passed up, and the air and fluid in the abdomen should be evacuated.

CASE OF
DIABETES MELLITUS,

WITH NUMEROUS OBSERVATIONS,
AND A REVIEW OF THE PATHOLOGY AND
TREATMENT OF THIS DISEASE.

By JOHN PERCY, M.D. (Edin.)

Physician to the Queen's Hospital, and Lecturer
on Organic Chemistry at the Royal School of
Medicine and Surgery, Birmingham.

(Continued from page 54.)

*Record of Chemical observations made
in respect to Merchant.*

I EXAMINED the urine at repeated intervals, from the time of his admission to that of his death. It had the ordinary properties of urine in diabetes mellitus. Colour pale straw. Without sediment. Delicate mucous cloud. Odour *sui generis*, and not urinous. Acid. It furnished well-crystallized grains of grape-sugar, by exposing the syrup obtained by evaporation over the steam-bath to the air for several days. Crystals of uric acid were separated by the addition of hydrochloric acid. At first, I was unable to detect urea, but afterwards I was enabled to separate well-formed crystals of nitrate of urea. The specific gravity will be found by reference to the table. In respect to the proximate analysis of diabetic urine, there are three points on which I shall offer some observations, viz. the determination of the *water*, of the *sugar*, and of the *urea*.

1st. Of the dermination of the water.

—The amount of water is usually estimated by evaporation over the steam-bath; and the data upon which the well-known table of Dr. Henry is founded were obtained in this manner. The loss occasioned by such evaporation is regarded as water. For practical purposes merely, this truth is sufficiently accurate; but it is not satisfactory to the analytical chemist. The following comparative experiments, performed with the greatest attention to accuracy, will shew that at the temperature of boiling water decomposition of the organic matter of the urine is effected. Even in vacuo, decomposition in a slight degree takes place; and if diabetic urine be evaporated over strong sulphuric acid, in the receiver of the air-pump, the acid acquires a pale brown colour.

I evaporated 500 grains of diabetic urine, sp. gr. 1035·3. 62°F, over strong sulphuric acid in the exhausted receiver of the air-pump, April 22d, 7 P.M.

Weight, May 3d, 7 P.M. 46·3.
Ditto. May 7th, 1 P.M. 46·3.

The desiccation in this case must have been complete. The extract was nearly colourless, and was full of small bubbles.

500 grains of the same urine were evaporated over the steam-bath, April 23d, 11 A.M. The bath consisted of a tin vessel, the cover of which contained a circular aperture just sufficient to receive a Berlin capsule.

Weight at 4½ P.M.	48·7
6¼ "	46·6
9¼ "	45·1

The desiccation was continued on the following morning,

Weight at 12 A.M.	44·7
2½ P.M.	44·1
8½ "	43·5

The residuum was hard when cold, and had a dark brown colour.

Evaporation in vacuo	46·3
" over steam-bath	43·5

Difference	2·8
------------	-----

Again, evaporation of diabetic urine, sp. gr. 1027°, continued for many hours over the steam-bath. 200 grains employed.

1st weighing	13·2
2d "	12·2
3d "	11·7
4th "	11·6
5th "	11·4

It was not ascertained whether 11·4, the result of the fifth weighing, was the quantity which would not admit of further diminution in weight by continued evaporation. The same objection, on the ground of accuracy, will also apply to the drying apparatus of Berzelius, represented and described in Plate 7, Fig. 31, Tome 8ième, *Traité de Chimie*. From the specimens of diabetic urine subjected to experiment, I obtained well crystallized grape-sugar.

Again, evaporation of 200 grains of urine, containing an excess of urea, over the steam-bath, sp. gr. 1027°.

1st weighing	12.5	6th weighing	10.2
2d "	11.7	7th "	10.1
3d "	11.0	8th "	10.0
4th "	10.6	9th "	9.8
5th "	10.3	10th "	9.6

The experiment was begun at 11 A.M. and continued until 10 P.M. of the same day. The preceding experiment, together with numerous others of a similar kind, have induced me always, in delicate analyses of the urine, in which I wish to attain extreme accuracy, to determine the amount of water by evaporation in vacuo over strong sulphuric acid at the ordinary temperature. 500 grains of Merchant's urine, sp. gr. 1040°, left, after exposure to the influence of strong sulphuric acid in vacuo for nine days, 51.63 of pale brownish yellow frothy extract. Now, a wine pint of diabetic urine, of sp. gr. 1040°, = 7581.3 grains; and, according to Henry's Table, should contain 766.4 of solid matter. Therefore, 1000 grains of such urine should furnish 101.08 of solid matter. However, by desiccation in vacuo, as mentioned above, I obtained from 1000 grains of such urine 103.28. Excess in the latter amounts to 2.18 grains.

2d. Of the determination of the sugar. In order to procure crystallized grape-sugar from diabetic urine, it is essential to leave the brown syrup obtained by evaporation over the steam-bath, exposed to the air, sometimes for several days. In this case the crystallization does not depend upon any further degree of evaporation, which may be effected by such exposure, but is connected with a molecular change, which, when once excited, proceeds with considerable rapidity. The attraction of cohesion in the syrup interferes with the freedom of molecular motion essential to rapid crystallization. I have had syrup of diabetic urine, which has not crystallized in less than a fortnight.

I have obtained beautiful and almost colourless grains, composed of minute and perfect crystals, by exposing the syrup left by evaporation in vacuo. In the estimation of the quantity of sugar I have resorted to the process of fermentation.

Oct. 26th.—To f*ʒ*ij. of Merchant's urine, sp. gr. 1036°, I added a minute quantity of yeast. The gas evolved was first passed over chloride of calcium, and then into Liebig's potash bulb apparatus, just as in ordinary organic analysis. The urine was contained in a two-necked bottle, one neck of which was connected with the chloride of calcium tube, whilst the other received a small tube drawn out to a capillary extremity, which was introduced below the surface of the urine, the other extremity communicating with the atmosphere. By this arrangement, I could, as in an organic analysis, cause the carbonic acid remaining in the bottle after fermentation to pass into the potash apparatus, by inhaling in the usual way with a pipette. Fermentation was soon established, and the gas was disengaged with regularity. The corks used in adjusting the tubes to the two-necked bottle were varnished. When the gas ceased to be evolved, as indicated by the rising of the solution of potash, the potash apparatus was detached and weighed, the carbonic acid remaining in the bottle and chloride of calcium tube having been previously displaced by air, in the manner described.

After fermentation	.	.	769.94
Before "	.	.	737.02
			32.92
Increase, due to carbonic acid.			

One atom of grape sugar ($C_{12}H_{22}O_{11}$) 199.44* ($C=6.12$.)
One atom of ditto by fermentation, yields $4CO_2$ = 88.48

∴ 88.48 : 199.44 : : 32.92 : 74.203.
∴ f. *ʒ*ij : 74.203 : : f. *ʒ*xvj : 395.749 grains of grape-sugar
in a wine pint of urine.

Now, according to Henry's Table, one pint of such urine contains 689.6 of solid matter. Hence, in this quantity we should have 689.6 — 395.749 = 293.851 of *organic* and *saline* matter, besides *sugar*.

Nov. 9th.—In precisely the same manner, I fermented 1000 grains of Merchant's urine, sp. gr. 1040°.

* At 212° it loses $2H_2O$.

Potash apparatus, after fermentation, weighed	810.62 grains
Ditto before	781.91
Increase, carbonic acid	<hr/> 28.71

Hence, this quantity of urine contained 64.714 grains of grape-sugar. 1000 grains of this urine, we have seen, furnished, by complete desiccation *in vacuo*, 103.26 grains. A wine pint would contain 471.765 grains of grape-sugar. Now, a wine pint of Merchant's

urine of sp. gr. 1036°, contained 395.749 grains. We have, then, in a wine pint of urine of sp. gr. 1040°, 76.016 grains of sugar more than in the same measure of urine of sp. gr. 1036°. Now from Henry's Table we learn, that a wine

pint of urine, sp. gr. 1040°, contains, of solid matter	766.4 grains
and Ditto Ditto 1036°, Ditto	689.6
	<hr/> Difference 76.8

This excess, then, would appear to be entirely grape-sugar, as will be seen from the statements immediately preceding. $76.8 - 76.016 = 0.784$.

In regard to the method of estimating the quantity of sugar in diabetic urine by the process of fermentation, it is alleged that two sources of error exist, viz. the production of carbonic acid from the yeast, and the resolution of the urea which may be present into carbonate of ammonia. I admit this allegation in a strictly chemical point of view; still, I am convinced that the absolute amount of error from these sources is exceedingly small, and may generally be safely neglected. In the first place, a minute quantity of good yeast is sufficient to excite fermentation; and, from experiments performed over mercury with a view to estimate the amount of carbonic acid evolved from the yeast alone, I am satisfied of the truth of what I have just advanced. Concerning the second source of error, I may state, that, in the case of Merchant, it must, indeed, have been small, for urea existed only in minute proportion, as will hereafter be clearly seen in the detail of an ultimate organic analysis of the residuum obtained by evaporation *in vacuo*. Besides, all the carbonate of ammonia generated and dissolved in the urine would not readily pass over with the carbonic acid. Dr. Christison states that the test of fermentation is so delicate, that one part of diabetic sugar in 1000.0 of healthy urine, sp. gr. 1030°, may be detected by it, the carbonic acid evolved being collected over mercury in a graduated receiver.—(Library of Practical Medicine, vol. iv. p. 249.)

3. Of the determination of the urea.

—This principle, frequently, cannot be detected in diabetic urine in the usual manner, by evaporation and the addition of nitric acid; the sugar preventing the precipitation of the nitrate of urea, or the urea existing only in small quantity. At one time the opinion prevailed that urea was generally absent from diabetic urine, but this opinion has, of late, been proved to be erroneous. To Dr. Kane we are indebted for the knowledge of the fact, that, when nitric acid fails to precipitate the urea in the state of nitrate, at the ordinary temperature, this salt is readily separated at a very low temperature. Accordingly, by the aid of refrigerating mixtures, urea may always be precipitated by the addition of nitric acid, in excess, to diabetic urine, reduced sufficiently by evaporation. Sometimes, however, a considerable time is required in order to effect this precipitation of nitrate of urea.

The following experiments were carefully made upon this subject:—

1. To fʒss. of Merchant's urine, sp. gr. 1040°, I added, fʒss. of nitric acid, diluted with the same measure of water. I introduced the mixture, contained in a thin glass-tube, into a mixture of snow and dilute sulphuric acid for three-quarters of an hour, the thermometer indicating — 2 F. No crystallization of nitrate of urea occurred, nor was the transparency of the liquid in the least degree disturbed.

2. I then exposed a mixture of fʒij. of this urine, and fʒij. of the strongest and pure nitric acid, to the same temperature for the same period, and with the same result.

3. I mixed f3ij. of healthy urine with an equal bulk of the same nitric acid, and exposed the mixture to the same circumstances. A considerable quantity of beautiful and nearly colourless crystals of nitrate of urea was separated, and remained on the following day.

4. I washed the residuum from 500 grains of Merchant's urine, evaporated over steam-bath, with cold rectified spirit. I evaporated the spirituous solution to a syrup, to which I added a small quantity of distilled water. I thus obtained f3ij. of solution, which, mixed with f3ij. of strong nitric acid, and left in the same frigorific mixture all night, presented, on the following morning, beautiful crystals of nitrate of urea.

Occasionally, urea may be readily separated in the state of nitrate by washing the extract of diabetic urine with cold rectified spirit, evaporating the spirituous solution, re-dissolving the residuum in a small quantity of water, and then proceeding in the ordinary way. Sometimes the urea may be separated at once, as nitrate, by the addition of nitric acid to the syrup. A short time ago, I succeeded in this manner in separating urea from diabetic urine of sp. gr. so high as 1045°. I could not detect a trace of urea by acting upon the residuum of Merchant's urine with common æther; though from the residuum of healthy urine this menstruum readily dissolves out the urea, and, by evaporation, leaves long and beautiful crystals. One part of pure urea, I find, dissolves in 63 parts of common rectified æther (of sp. gr. 759·3 59° F.), at 49° F. The usual mode of estimating the quantity of urea is, I am persuaded, from numerous experiments, incorrect in a very appreciable degree. I have ascertained the amount of error, but, on the present occasion, it would be superfluous to enlarge upon this subject. The absolute amount of urea may, probably, be inferred from the ultimate analysis, to which I have before alluded, and which will be found in the sequel.

The determination of the fixed saline ingredients of diabetic urine, by the process of incineration, is tedious, and requires considerable attention. The residuum of evaporation swells up exceedingly on the application of heat, so that a large platinum crucible must be

employed. The carbon gradually burns away, and leaves a delicate skeleton of saline matter, from which any remaining portion of carbon may be removed by the very cautious addition of nitrate of ammonia. To prevent any loss by projection, it is advisable to replace the cover of the crucible immediately after the introduction of each particle of nitrate of ammonia. I have, previously to incineration, sometimes destroyed the sugar and similar organic matter, by evaporating the urine with nitric acid. One source of error, in this mode of determination, may be the volatilization of a minute quantity of chloride.

Analysis of 1000 grains of diabetic urine, sp. gr. 1040°.

Water	896·740
Sugar	64·714
Urea, uric acid, colouring matter, volatile saline matter, and other organic constituents					32·746
Chlorides	2·5
Sulphates	1·5
Alkaline carbonate, probably derived from the decomposition of an organic salt					0·5
Phosphates of lime and of magnesia					1·3
					<hr/>
					1000·000

Ultimate analysis of the residuum of diabetic urine of sp. gr. 1036°. I believe this was the sp. gr., though I cannot be certain to two or three degrees.

The residuum was obtained by evaporation *in vacuo*, and then allowed to crystallize completely by exposure to the air. Thus crystallized, it was again desiccated *in vacuo* over strong sulphuric acid, for several weeks. The nitrogen was determined by the ingenious method of Varrentrapp and Will, described in the Philosophical Magazine, Vol. 20, p. 216. Two analyses were made, with the greatest attention to accuracy, with chromate of lead. The amount of fixed saline constituents was determined by incineration.

Hydrogen	.	.	.	6·360
Carbon	.	.	.	39·594
Oxygen	.	.	.	49·114
Nitrogen	.	.	.	1·179
Residuum	.	.	.	3·753
				<hr/>
				100·000

The weighings extended to thousandths of a grain. Dividing by the respective atoms (C estimated as 6.125, and N as 14.186, Berzelius), we have—

Hydrogen . . .	6.360
Carbon . . .	6.454
Oxygen . . .	6.139
Nitrogen . . .	0.083

Hence, it is clear that, even admitting all the nitrogen to have existed in the state of urea, only a very small proportion of this constituent was present. In 100.0 parts of organic matter, exclusive of fixed saline matter, we should have—

Hydrogen . . .	6.607
Carbon . . .	41.137
Oxygen . . .	51.029
Nitrogen . . .	1.224

By comparing these results with those obtained by our honoured countryman, Dr. Prout, we find that the organic matter of Merchant's urine, exclusive of sugar and azotised matter, has nearly the composition of grape-sugar. Thus,—

Dr. Prout's Analysis of Diabetic Sugar.

Hydrogen . . .	6.67
Carbon . . .	40.00
Oxygen . . .	53.33

Of the indeterminate organic matter of urine there is little of a satisfactory kind at present published. We can conceive that, generally, it may vary much in respect to ultimate composition, according to variation in diet. In diabetes mellitus, however, its composition is, probably, less liable to variation; for we know that specimens of urine, in this disease, and from different patients, closely resemble each other in physical as well as chemical properties. I make this remark with due regard to exceptions.

There does not appear to have been great variation in the absolute amount of fixed saline matter in Merchant's urine. Three incinerations were carefully made, and the results are as follow:—

1. 1000.0 grs., sp. gr. 1036°, furnished 4.6
2. Do. do. do. do. 3.753
3. Do. do. 1040° do. 5.8

There is only one analysis of diabetic urine in the "*Chimie Pathologique*" of L'Héritier, p. 558. It differs considerably from my own, and the quantity of sugar is not clearly estimated.

L'Héritier's Analysis of 1000.0 parts, of sp. gr. 1042°.

Water . . .	931.200
Urea . . .	7.600
Uric acid . . .	0.080
Organic matters . . .	52.575
Inorganic salts . . .	8.545
	<hr/>
	1000.000

Of the 52.575 parts of organic matter, L'Héritier ascertained, by another analysis of the same urine, that 46.936 were sugar. The mode in which the sugar was determined is not mentioned. We are indebted to Dr. Christison for some valuable observations on the urine of diabetes, published in the *Edinburgh Monthly Journal of Medical Science*, No. 4, April 1841, pp. 233 et seq. They are as follow:—

Feb. 13th.—1000.0 grains, of sp. gr. 1048.5, contained 57.7 of sugar, and 12.6 of urea.

March 13th.—1000.0 grains of urine, from the same patient, contained 101.8 of solid matter, of which 69.9 were sugar, and 14.0 urea.

March 13th.—1000.0 of urine, of sp. gr. 1038.0, of another patient labouring under diabetes, contained 84.74 of solid matter, of which 50.5 were sugar, and 23.22 urea.

1000.0 grains of urine, in another diabetic case, of sp. gr. 1033°, contained only 2.0 grains of urea. The urine of the same man, four days afterwards, sp. gr. 1035°, contained 81.5 parts in 1000.0, of which 4.63 were urea. The urine of the same individual, two days afterwards, its quantity having increased, had sp. gr. 1032°, and contained, in 1000.0 parts, 40.8 of sugar, and 13.9 of urea.

Miscellaneous Observations on Merchant's Urine, sp. gr. 1040°.

1. By boiling for a few minutes, it became turbid, and greyish flocculent matter subsided. The turbidity was almost entirely removed on the addition of nitric acid.

2. Tincture of galls gave a flocculent lemon-coloured precipitate.

3. Boiled with bichromate of potass, green oxide of chromium was liberated (? with formation of oxalate of potass).

4. Sulphate of copper, boiled for some time with this urine, produced a dirty-greenish precipitate, and the supernatant liquid had a clear apple-green colour.

5. Nitrate of silver, heated with this urine, was decomposed, with the liberation of metallic silver.

In the last stage of the disease, as is usual, the sugar disappeared from the urine, which contained an abundance of urate of ammonia, and of deep brownish-red crystals of uric acid.

Dec. 29th. — Urine passed on the morning of the 28th. Sp. gr. 1025°. Brown. Copious deposit, on cooling, of amorphous sediment, immediately soluble in hot water (urate of ammonia). Filters clear.

31st. — Precisely similar in appearance to that passed on the 28th. Odour urinous. Reddens litmus. Sp. gr. 1013°. Copious deposit of urate of ammonia and crystals of uric acid. 500·0 grains, evaporated over the steam-bath, left 24·3 of brown urinous syrup. This urine, simply by careful evaporation, furnished, on cooling, long and beautiful crystals of urea. The syrup, on the addition of nitric acid, became a solid crystalline mass. To 500·0 grains of this urine I added, without previous evaporation, f3vj. of strong nitric acid. On the following day an abundant crop of crystals of the nitrate of urea had separated. I fermented f3viij. with yeast. Three days afterwards I distilled over f3vj., which I mixed with carbonate of potass, and then redistilled. The product was received in a small tube, containing carbonate of potass. Instantly, after agitation, was separated a stratum of alcohol, which burned with a blue flame.

Jan. 2d. — Merchant's last urine. Brown. Slightly turbid. Acid. Sp. gr. 1020°. With pale brown deposit of urate of ammonia. No sugar was detected by fermentation. Long and beautiful crystals of urea were readily obtained by treating the evaporated urine with cold æther.

Examination of Merchant's Breath, in respect to Moisture.

Nov. 11th. — He came in a car to my house, this morning, at 10½ A.M. I caused him to expire very carefully

through one of Liebig's chloride of calcium tubes, filled with chloride. What he expired was passed into a graduated receiver over water, so that the volume of breath could be precisely ascertained. I allowed him only to expire a small quantity through the tube at a time; and, during the experiment, he breathed out freely several times. I weighed the tube after the passage through it of fifty cubic inches. I obtained 0·41 increase. Mr. Clay, one of the pupils of the hospital, was then made the subject of a precisely similar experiment, and the same quantity of increase occurred. The temperature was 54° F., and the weather appeared to be damp.

[To be continued.]

THE
HUMAN SKIN AND ITS
PATHOLOGY.

BY OTHO WUCHERER, M.D.

Member of the Royal College of Surgeons in
London; Rua de Boa Vista, Lisbon.

(For the Medical Gazette.)

(Concluded from page 59.)

THAT the secretions of the skin are necessary for the maintenance of a healthy composition of the blood seems to be proved sufficiently by physiological and pathological facts. The importance of these secretions in that respect might be inferred already from the considerable quantity of matter secreted, and from the antagonism between the skin and inner organism in respect to their secretions. In the skin two secretions are said to take place, that is, besides that of the cyto-blastema, in which the cells of the epidermis originate, viz. that of a sebaceous kind by the sebaceous follicles, "and that of the sudorific glands, commonly termed perspiration, when it takes place more profusely and visibly, for generally it is of a vaporous kind, and therefore not perceived: hence the term insensible perspiration, so frequently found in works on pathology. A secretion that is also vaporous, and shows in other respects analogy to that called perspiration, is that of the lungs. For detailed accounts of these secretions we refer to Johannes Müller's Physiology; and of their chemical composition to the 9th vol. of Berzelius's Chemistry. Müller says, that the

chemical analysis of these secretions had as yet not cast any light on their value. The serum secreted by the follicles is supposed to be designed to make the skin soft and pliable. Perspiration is known to answer the purpose of regulating the temperature of the body. At the same time, it depends on the temperature of the atmosphere, as well as on the quantity of water which the latter contains suspended or dissolved. If the atmosphere is warm, the skin secretes freely; if cold, it secretes less. But when the skin secretes freely, the kidneys secrete less; and when it secretes little, the kidneys secrete more; so that both organs are capable of taking, to some degree, one another's place. This may explain the greater frequency of cutaneous diseases in warm climates, and the comparatively less frequency of diseases of the urinary organs in those parts; whilst cutaneous diseases were observed to be less frequent in cold climates. If perspiration is prevented to some degree in an individual at the same time that his body attains higher temperature, as by exercise, he feels uncomfortable, and considerable anxiety may be the consequence in some persons. I have heard several complaints in this country that the Indian-rubber cloaks had this effect, and that Indian-rubber shoes made the feet feel hot and uncomfortable. The skin stands in sympathy with many internal organs, as observed in daily experience; and, as Müller remarks, it presents an extensive field from which to act on the nervous centres in their morbid affections. We refer to his work for detailed accounts of these sympathies. The different parts of the skin show a consensus with one another, which seems explicable only by action of nerves. Henle says, in scabies, parts of the skin have pustules to which the acarus has not reached. A blister does not act solely on that part of the skin it occupies, and it is often used to augment the secretion of the whole skin. If tartar emetic ointment is rubbed in a part of the skin, there often appear pustules in other parts of the skin. The influence of nerves on the skin and its secretions is evident in diseases of the mind, or nervous centres, but also in affections of other organs; and very often we draw conclusions from the state of the skin on that of the powers of a patient, &c.

That the temperature of the skin depends in part on nervous influence is shown by experiments, and seen in many diseases. But it is needless to quote more striking proofs of the dependency of the skin and its secretions in particular on nerves. Many facts that show this connexion exhibit at the same time the laws of reflex function discovered and illustrated by Marshall Hall and F. Müller.

The description of the epithelia we gave after Henle, and did not mention at the same time some observations by Reichert, which seem to prove a material difference in respect to manner of development and functions between the epithelium of the skin and the so-called epithelium of the intestinal canal. Burdach says somewhere, that the nervous system served often as an asylum for our ignorance, and that to it all changes were attributed which we were otherwise unable to explain. It is remarkable, that about the same time, when numerous physiologists were employed to elucidate the functions of the nervous system by experiments, the independency of cells from nervous influence should have been so clearly and universally illustrated. The cylindrical or conical cells that cover the inner surface of the intestines, regarded by Henle as a kind of epithelium, Reichert has endeavoured to prove to be the mucous membrane of this canal, at least the membrane which possesses the property of absorption. His reasons for this opinion are the following:—In the first place, the structure described by Henle as an epithelium is deposited by the yolk of the ovum on the inside of the intestinal tube, and is no secretion like the epithelium of the skin. Besides, Reichert observes that in the frog the intestinal canal consists only of a muscular membrane and the layer of cells corresponding to the membrane now in question. If this is not the organ of absorption, which then? Reichert could find no blood-vessels or nerves in this structure, but this cannot diminish our opinion of the importance of the cells; it serves us only as a proof of the important properties of cells in general; for the knowledge of which we are indebted to Schwann in the first place, and also to Müller, Reichert, and others. Müller considers Schwann's discovery the greatest made in physiology for a

long period. After having given the description of the formation of the mucous membrane, taken from Reichert's manuscript, Müller says he avoided the scrupulous term "epithelium," because this structure might have a higher importance than was generally supposed; and he seems induced to this opinion by Reichert's ingenuous observations. The independency of the cells that compose the absorbing tunic of the digestive tube reminds one forcibly of that possessed by the cells of the yolk in the ovum to develop themselves, tending to form the organs of the embryo. It shows, at the same time, a striking analogy to the properties of the cells in plants, and gives a proof of the correctness of Schwann's opinions. If Reichert is right in considering the cellular covering of the digestive tube as the organ of absorption, there is a great difference in its designation and that of the epidermis, supposed to be principally intended as an envelope for the body, which, in one or the other form, all living bodies seem to possess, and by which they exclude themselves from foreign influences. However, these foreign influences cannot be entirely overcome—they would act on the body if the latter did not pay a tribute; this tribute is the epidermis, which is composed of cells, the lowest order of organic development, nature thus avoiding the sacrifice of more developed orders. Before Schwann's discovery, the vibratory epithelium was found out; and it gives another example of vital motion without nerves. For accounts of it, as well as of the purpose it is said to answer, I refer to the works on physiology by Müller and R. Wagner. The latter treats of analogous vital motions observed in plants and animals, and observes that he intends to publish a separate work on these phenomena.

If you consider that the skin is so accessible to anatomical investigation, and that its diseases are so open to view, it must appear remarkable that our knowledge of its anatomy and pathology should have remained so long imperfect. The fact that diseases, which present themselves in other organs in such a number of various symptoms, caused but a limited number of changes in the skin, might have led to an inquiry into the structure of the skin, particularly since it made the

classification of these affections so difficult. Already, Lorry, and many other authors on cutaneous affections, considered the sebaceous follicles a frequent seat of those diseases which appear as circumscribed inflammations of the skin. One author after the other copied this remark, without inquiring further into the subject. Even Schönlein, who endeavoured to construct a natural system of diseases, gave very artificial diagnostic signs for the discrimination of cutaneous diseases. He calls the halo (which term he censures) at the base of the pustules, vesicles, &c. pericarpium; and distinguishes a pericarpium simplex, bearing only one pustule, vesicle, &c. called the fruit, and a pericarpium commune, bearing several fruit. But he mentions nowhere that observation in respect to the sebaceous follicles made already by Lorry (Dr. F. L. Schönlein's *Allgemeine und specielle Pathologie und Therapie*, St. Gallen. Im Litteratur Comptoir, 1839). An opinion formerly entertained (Peter Frank), that the seat of cutaneous diseases could never be sought in the epidermis, since it had no vitality, possessing no vessels and nerves, can of course no longer be admitted since Schwann's discoveries. And Schwann's assertion, considering the origin of all tissues in the healthy animal body from cells, has been shown by J. Müller to be equally true for morbid tissues (see the translation of his work, *Ueber den feineren Bau und die Formen der krankhaften Geschwülste*, Berlin 1838). According to Henle, the following changes may take place in an effusion of lymph consequent on inflammation or other causes.

1. There appear cells, which develop themselves in the same way as those of the tissue surrounding the effusion, and this is the process of regeneration and hypertrophy.

2. The cells do not develop themselves in the manner of those of the tissue into which the effusion took place, but in that corresponding to the manner of development in cells of some other tissue in the body, as in ossification, induration, &c.

3. The cells develop themselves in a manner altogether strange to the body; and here their development, independent of the latter, is particularly evident, since the structures formed by these cells tend to dispossess the an-

nexing tissues: hence they are often called parasites.

These cells, if deposited in another part of the body, develop themselves always in this peculiar manner. Even if removed to other bodies, they develop themselves to constitute the same structures, as shown by Langenbeck's interesting experiments. He brought cells from a cancer of one body into the circulating system of another, and the disease appeared in the latter. This fact supports an opinion, defended by Henle, that the contagium of diseases is not their mere cause, but their actual germ. His reasons for this supposition are the following. Only living beings possess the capability of increasing by assimilation of strange matter: fermentation has been adduced as a proof against this law; but as the observations of Cagnard, Latour, and Schwann show, fermentation depends on the propagation of organic bodies of plants (*Torula cerevisiæ*, Turpin; the *sal aceti* of Leeuwenhoeck). A single cell of these bodies is sufficient to cause the development of an infinite number if brought into a substance favourable to their propagation. In like manner but a minimum of contagion is necessary to carry the disease from one individual to another. Harvey's sentence "*omne vivum ex ovo*," so frequently assailed for so many years back, seems to be true after all, according to the convincing experiments of Schwann, and Ehrenberg and Eschricht's observations; and if it is true, it supports the opinion adopted by Henle. It has often been observed that no one had ever seen a contagium: however, besides the analogy of fermentation, organic bodies resembling the lowest orders of plants and animals have been observed by Bassi, Audouin, Balsamo, Lomeni, and Montagne, to be the cause of a disease, on silkworms, the bearers of the contagium, or rather the contagium itself, a single cell taken from one animal being sufficient to produce the disease in another. Similar observations have been made by Hannover and Henle in respect to *Triton cristatus*, on which they found *vorticellæ* to form a destructive disease; by Ehrenberg in respect to fishes. Besides, there seems to exist a great analogy between the cutaneous diseases of animals and plants, the latter being caused by living bodies of the lowest

orders, as shown by Uenger. But as yet we are convinced of the existence of only one living contagium for the human body, the *acarus* known to cause the itch. A similar animal was found in syphilitic ulcers, but its relation to the contagiousity of the disease is yet dubious. Henle has collected many facts besides to defend his opinion, for which we must refer to his work, "*Pathologische Untersuchungen*, 1840." All these observations concerning the living contagium well deserve the attention of the profession, even if the conclusions drawn from them till now should appear problematical.

A structure I have not hitherto mentioned is the subcutaneous cellular tissue. Its contraction is considered to cause the *cutis anserina*. The elevations that appear in this case are formed by the sebaceous follicles. From each of these elevations remarked in *cutis anserina* you observe to proceed a hair. The contraction of the subcutaneous cellular tissue may also be regarded as the cause of an erection of the hairs observed in some cases. This erection of the hairs depends besides on the contraction of the cellular tissue, on their piercing the skin in an oblique direction, and their extending with their fixed ends into the cellular tissue. If the latter contracts itself, it moves the end of the hair, which having its *hypomorphion* in the opening of its follicle, is erected. That a single hair proceeds from each nodule in *rubeola* was already observed by Wedekind; Willan describes a *lichen pilaris*. Sometimes the hair is only visible by means of the magnifying glass. On the skin of almost all persons you perceive slight elevations, of a white, or when rubbed of a reddish colour: they consist of a crust of almost pellucid substance. If you lift this crust off, you perceive an elevation on its inferior surface, which corresponds to a depression on the spot of the skin from which it was taken. In the depression you observe a hair, folded up in a tortuous manner, which proceeds from an opening at the bottom of the depression. If the crust is moistened in water, and brought under the magnifying glass, you perceive it to consist chiefly of epithelium cells. To explain the formation of these elevations, and what is evidently their consequence, the folding up of the hair, we must suppose that, first, the

hair of each of these thus affected follicles had fallen out; perhaps the secretion of the sebaceous follicles was at the same time altered, so as to obstruct the opening of the follicle, through which then the new hair could not pass, and continuing to grow, it became folded in that manner. Whether these elevations can be the cause of any inconvenience I do not know; perhaps, however, some species of prurigo might find in them their explanation. That the disease called acne depends on an obstruction of the opening of these follicles is well known; in the white matter you can often press forth from these follicles, you generally find one, seldom two small hairs. If the white substance is moistened in water, you find it to consist of cells of epithelium when you regard it under the microscope. The follicles may be extended by their secretion, if its passage outwards is prevented, to an enormous size, and form thus, according to some, bodies that have great resemblance to those encysted tumors known under the name of atheroma. From the middle of variola pustules you often find to proceed a hair, but the peculiar cellular structure of these pustules is not satisfactorily explained. Miliaria, Rosenbaum (see the article Miliaria, in Blasius Handwörterbuch der Chirurgie. Berlin, 1838) has declared to be an affection of the sudorific glands, which, he says, become inflamed, and form slight elevations over the surface of the skin. The swelling of the glands he considers the cause of obstruction in their secretory ducts, which is a new cause of enlargement of the glands. The vesicles that appear on the skin he declares to be the extended secretory ducts of the glands. And so almost all cutaneous diseases have been regarded of late as affections of one or other organ in the skin; but every one must acknowledge that, as yet, very little is known of the pathological anatomy of these affections: before a positive foundation is laid herein the classification will remain difficult and vague. Almost every year there appear new works on the subject, and every author thinks himself justified to produce a new system of cutaneous affections, and to invent new names, of which there is already such a superabundance. The observations of Breschet and R. de Vauzeme, of Gurlt,

Helwig, Berres, Zeis, Henle, Müller, and Bidder, have enlightened our knowledge of the healthy state of the skin; and it is to be hoped that their discoveries will lead to a more successful investigation of cutaneous diseases.

CASE OF
PERFORATION OF THE STOMACH,
AND CONSEQUENT PERITONITIS.

To the Editor of the Medical Gazette.

SIR,

WILL you oblige me by publishing the following case in your valuable journal.

Thomas Hayes, æt. 52, a porter, had been in delicate health five or six months, and had been observed of late years "to age" very much. For some weeks past he complained of frequent griping pains, loss of appetite, looked care-worn, had slight cough; he was not evidently ill, and continued at his work. He returned home on the evening of Thursday the 30th of March, apparently not worse than usual.

About half-past seven he complained of being very poorly, was cold, and shivered; he got some warm tea, and went to bed. In about an hour an alarm was given that he was very ill, and a neighbour who went in found him at the bed-side vomiting violently, and complaining of great pain in the belly. The matter ejected is said to have been very offensive, dark coloured, and frothy, but contained no blood. After a while he felt a little relieved, got into bed again, and did not agree to the proposal of sending for a doctor, as he thought he should soon be better.

He passed a very bad night, but I could not learn the particulars. In the morning, Mr. Hatton, surgeon, saw him, and considered him sinking. Mr. Strickland, house-surgeon of the Chorlton-upon-Medlock Dispensary, who saw him also, found him nearly pulseless, the countenance expressive of exhaustion rather than of pain; the eyes were sunk; the extremities cold; voice just audible. The belly was very tense, but he did not complain of pain when it was pressed; in fact, he was just dying, and nearly insensible. He gradually sank, and died at 11 A.M. on Friday, seventeen hours after the *apparent* commencement of the disease.

The imperfect account which I have been able to gather clearly justified suspicion that it might be poison. They were just those symptoms of irritant poisoning which a non-medical observer would be likely to remark: vomiting, pain, and exhaustion quickly following the taking of food, constancy in the character of the symptoms, and rapid progress to a fatal termination. There were no moral circumstances to lead to such a surmise; but a case so ambiguous required further investigation. By Mr. Strickland's kindness I was enabled to witness the inspection, about fifty hours after death.

Externally we observed nothing remarkable, except lividity of the organs of generation. The man looked considerably older than he was reported to be; his features were contracted and sharpened; his teeth very much decayed.

The abdomen was tympanitic, and, when opened, the whole peritoneal surfaces were found crimsoned with inflammation; the intestines glued together, though not firmly, with recently effused lymph; about two quarts of serous purulent fluid, of very offensive smell, was in the peritoneal cavity. This fluid caused sharp smarting of my hands (my skin is very thin and tender); in it were observed a few currants, which had escaped, together with a few ounces of greenish-yellow bile, from the stomach. Between the stomach and liver, and especially behind the stomach, firmer adhesions had formed, but they were easily torn through; when we saw a perforation both on the anterior and posterior surface, just at the edge of the lesser curvature, about two inches from the cardiac orifice.

On removing the stomach and opening it, we could find no trace of ulceration or softening, or any disease of its mucous membrane, except a little reddening, and that probably cadaveric. At the lesser curvature there was an irregular-shaped hardened mass, about an inch and a half thick, very firm, and studded with tubercular matter. In the middle of this mass was a cavity, apparently the empty sac of an abscess, which communicated with the stomach by an opening of nearly an inch diameter, with irregular edges, not evidently ulcerated. It communicated also with the peritoneal cavity by

the two openings already mentioned, which were each not quite large enough to admit the little finger, and had hard thick edges.

The stomach, although there had been violent vomiting, was not empty; it contained about half a pint of pulaceous matter, consisting principally of half-digested potatoes. The intestines, though highly injected externally, showed no disease within. There was an unusual quantity of chyme in the small, and of feces in the large intestines. The colon was much distended with air.

It was reported that this man had had long-continued suppression of urine; this is not probable, for the bladder was nearly empty, and the kidneys appeared quite healthy. The liver was rather hardened on its surface, but appeared healthy within.

The heart and lungs were healthy; the latter were congested, but this was probably a cadaveric appearance. The abdominal vena cava was remarkably empty; the right side of the heart, however, contained its usual quantity of semi-coagulated blood.

I presume there can be little doubt about the nature of this case. It is evident that the disease was of long standing, and of insidious progress. I think it probable that a tuberculous abscess had formed, that it opened by ulceration, and allowed the escape of the gastric contents into the abdomen on the evening preceding death; that the sensation of cold complained of was a rigor previous to the giving way of the abscess, and that the peritonitis was excited by the irritation of the escaped bile and other contents of the stomach.—I am, sir,

Your obedient servant,
P. H. HOLLAND, M.R.C.S.L.

Manchester, April 4, 1843.

REMARKS
ON
CERTAIN DISEASES OF THE EYE.

BY JOHN CHARLES HALL, M.D. F.L.S.
Member of the Royal College of
Surgeons, London.

(For the London Medical Gazette.)

Pterygium.

THE name of this affection of the eye is derived from πτερυγ, a wing. It is

seldom seen by the surgeon in its incipient state, and very frequently acquires a considerable magnitude before the patient solicits relief. It arises without pain, and is of very slow growth. In the end, however, it creeps from the corner of the eye over the whole cornea, and the vision becomes impaired, and at length altogether obscured. Unless affecting the conjunctival covering of the cornea, the disease only produces a trifling deformity, and does not occasion any impediment to vision. It always assumes a triangular form, which, says Scarpa, "ought to be referred to the adhesion of the lamina of the conjunctiva becoming stronger as it advances from the circumference towards the centre of the cornea." It is a disease which generally makes its appearance at or beyond the middle period of life: it has, however, been noticed shortly after birth; and I have at this moment two cases of it under my care—one in a young lady of seventeen, the other in a boy of twelve. In the boy it followed an attack of inflammation, induced by some lime which had been thrown into the eye; and this certainly strengthens the opinion of Beer, who believed that lime or stone dust produced pterygium, as he most frequently saw it in masons' labourers. The varieties of pterygium are three—

1. The adipose.
2. The fleshy.
3. The membranous.

The first is of a white soft texture, something like dirty fat; the second resembles muscular fibre; and the third variety exhibits a partial thickening of the ocular conjunctiva, with two or three large vessels meandering upon the diseased mass.

These are the only varieties I shall notice. I have never seen a carcinomatous or malignant pterygium, and in all probability never shall. Beer remarks, "that Scarpa's belief in the existence of cancerous pterygium requires confirmation." Mr. Travers does not even mention this form of the disease, and Mr. Middlemore "is not inclined to admit the existence of such a variety." Of course no one attempts to deny that this, in common with many other morbid growths, however simple at first, may become malignant from improper management.

Treatment.—In the treatment of this disease astringents and escharotics are

of little use, and frequently do more harm than good; much time is lost by their employment, during which the disease daily advances, and in the end it is discovered that it ought to have been removed at once, instead of wasting weeks, perhaps months, in such inefficient trifling. The removal of the diseased part ought at once to be recommended; this caution is, however, necessary, viz. that the part of the morbid growth extending over the cornea must not be incised. Should the surgeon incautiously do this, during the healing of the divided parts an opaque deposit will take place, which may prove even worse than the original disease.

CASE.—Miss U., residing near Tuxford, consulted me for a pterygium growing from the outer cornea of the right eye, and extending over two-thirds of the cornea. This young lady was requested to sit on a chair, and whilst an assistant separated the lids, I passed a narrow-bladed knife, having its back towards the cornea, between the pterygium and the sclerotic coat. The pterygium was then separated from the sclerotic as far as the margin of this transparent structure, and the flap thus formed was raised by a little hook, and cut off with a pair of scissors. The eye was washed with warm water, and after a day or two with mild astringent lotions. Some ragged portions of the conjunctiva were afterwards removed with the scissors, which I think a better and far less painful plan than attempting to destroy them by powerful caustic substances.

After the operation the eyelids must be closed, but not tightly fixed upon the globe, with a bandage. The granulations must be encouraged or repressed, as circumstances may point out, and care taken that the eyelid does not become adherent to the eyeball.

There are other modes of performing this operation. Mr. Middlemore employs both a scalpel and probe-pointed scissors; others pass a curved needle and ligature beneath it, and obviate the risk of wounding the eyeball. In this, as in every other operation, many plans have been proposed. Knives, concave and convex, blunt and sharp, spear and probe-pointed lancets and scissors, needles and ligatures, have all their respective advocates; but the plan I have ventured to propose is very simple, and can be very

easily performed if the hand is steady ; and if it is not so, the sooner a man gives up operating the better, both for his own sake and also for that of his patient.

Pterygia are more frequent in warm climates than in this country. It very often happens that the disease which has been advancing slowly for years stops at the edge of the cornea, and spreads no further during the life-time of the patient. Under such circumstances I strongly advise that no operation should be performed. As the disease gives no trouble it ought to be left to itself, an operation only being required when it encroaches on the transparent portion of the eye.

Grove Street, East Retford,
March 27, 1843.

A NEW KIND OF PESSARY.

To the Editor of the Medical Gazette.

SIR,

I SHALL be obliged if you will allow me, through your pages, to call the attention of the profession to a pessary I have invented, which I believe to be preferable, in most respects, to all the various kinds at present in use. It consists of a piece of sponge cut into the form of a sphere, or, what is better, of an oblate spheroid, and tied up, by means of small twine or silk thread, in a circular piece of oil-skin, in such a manner that a small stem or tail is left half or three-quarters of an inch in length. The firmer kinds of sponge, which possess a good resiliency, are best ; and the oiled silk is closed as firmly as it can be by tying, but no extraordinary means are used, by cement or otherwise, to make it completely impervious to air.

When this pessary is compressed in the hand, the air contained in the cells of the sponge is gradually forced out at the neck, between the folds of the oil-skin. In this form it can be very easily introduced ; and when passed above the narrow part of the vagina and left at liberty, the elasticity of the sponge, and the pressure of the atmosphere together, cause air to re-enter the instrument, and it assumes its expanded form. The small tail hanging downwards will facilitate its removal at any time.

The chief advantages of this pessary are, I consider—

1. Its capability of being diminished in size during its introduction and removal.

2. Its softness, which is such that it can scarcely cause any of the effects of a foreign body.

3. Its small weight.

4. The tendency of its elasticity to keep it in its position ; for any sudden pressure of the viscera above will be spent in overcoming this elasticity, instead of forcing the instrument through the external parts ; and, moreover, such pressure will flatten it and make it wider, and thus render its extrusion the less possible.

As additional advantages I may mention its cheapness and its durability, which will be as great as that of the oil-skin ; and this, if requisite, can be applied double.

I have applied this pessary with perfect success up to this time, in three cases in which the uterus, except in the recumbent posture, had protruded entirely beyond the external parts for a number of years ; and in two of these cases various other pessaries had been tried, but in one case would not remain, and in the other could not be borne. As it is only about two months since I first applied these instruments, I will postpone any more particular account of the cases till another time.

Sponges are occasionally used as pessaries ; but as they become charged with mucus and other fluids, and soon decay or become offensive, and a source of irritation, they are only resorted to as a temporary expedient. A small sponge dipped, from time to time, in some astringent fluid, and applied in the beginning of prolapsus uteri, when it is yet but slight, as Dr. Denman suggested with the object of performing a cure, may, I believe, often fulfil that desirable intention. The pessaries which I have hitherto used I have made myself ; but I have now got Mr. Read, of Regent Circus, to make some, and he can supply them to medical gentlemen. Of course care will be required in adapting the size of these as well as other pessaries : when expanded these should be somewhat larger than a rigid pessary for the same patient.

I remain, sir,

Your obedient servant,

JOHN SNOW, M.R.C.S.

Frith Street, Soho Square,
April 7, 1843.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Dr. Hooper's Physician's Vade Mecum; or, a Manual of the Principles and Practice of Physic. A new edition, considerably enlarged and improved; with an Outline of General Pathology and Therapeutics. By WILLIAM AUGUSTUS GUY, M.B. &c. London, 1842. pp. 492.

THE late Dr. Hooper was a most successful author, and his works always enjoyed a high degree of popularity. This was especially the case with the present one, which possessed considerable merits of a peculiar kind. A plain enumeration of the most prominent and ordinary symptoms of a disease, with a brief notice of its causes, diagnosis, and prognosis, was followed by a detail of the most obvious and rational indications for treatment, and by rules for practice, and copious prescriptions, which were generally valuable, inasmuch as they emanated from the author's practical experience, and were not mere theoretical compositions, framed in the closet, in accordance with some chemical idea of what the action of medicines ought to be. Thus the work formed a guide to the treatment of disease, which might safely be trusted as far as it went, and which was admirably adapted for a large class of practitioners whose education had led them to be more solicitous about results than about the reasonings which lead to them; and who were, properly enough, desirous to know the easiest and quickest way of removing palpable symptoms; which is, in fact, no small portion of the practice of physic.

The present edition has received some very valuable additions from the pen of Dr. Guy, who has prefixed about 150 pages of introductory matter, including a scheme of medical study, directions for taking cases, and a brief but exceedingly well-digested outline of general physiology, pathology, and therapeutics. He has also added to the whole work whatever was necessary to bring it to the modern standard. Perhaps it would have been better had he adhered more strictly to the author's original model; preserving the con-

cise, detached, aphoristic style and regarding the book rather as a guide to the *practice* than to the *study* of medicine; for which latter purpose, however, Dr. Guy's introductory chapters are well adapted.

On the Theory and Practice of Midwifery. By FLEETWOOD CHURCHILL, M.D. M.R.I.A. Illustrated by upwards of one hundred highly-finished wood engravings by Bagge. London, Renshaw; Dublin, Fannin. 1842. 8vo. pp. 479.

DR. CHURCHILL tells us in his preface that he undertook this work at the request of the publishers, who wished “to offer to the student in midwifery a work embracing the modern discoveries in the physiology of the uterine system, with all the recent improvements in practice, in a condensed form, amply illustrated, and at a moderate price.” It is certainly a matter of congratulation that modern publishers find it worth their while to present us with books of so luxurious a character, and yet so cheap as the one before us, the thick smooth paper and clear distinct type of which will be duly appreciated by all who read by candle-light; whilst the numerous and exquisite woodcuts by Mr. Bagge add both to its ornamental effect, and to its utility to the student.

With regard to the literary portion, it is no small praise to Dr. Churchill to say, that this production deserves to rank with the recent works of Dr. Ramsbotham and Dr. Rigby. The introductory chapters contain a full account of the physiology of utero-gestation, and the development of the foetus, according to the most recent researches of Barry, Wharton Jones, and the continental physiologists, who have built up the modern science of embryology; whilst the body of the work, relating to the history and treatment of the different varieties of labour, and to the diseases of parturient women, leaves nothing to be desired for clearness of description and judicious rules for practice. It is, moreover, illustrated with copious statistical tables, shewing the success or fatality attending the treatment of the various deviations from natural labour, and intended to afford a numerical estimate of the value of various operations. We are aware that objections have

been raised to the correctness and impartiality of some of these tables; but this is a point on which it is not our province to decide at present. The parties interested in the dispute have published their statements in the pages of the *GAZETTE*, and the public must be the judge: at all events, we believe that no objection has been raised against their practical usefulness.

We must observe, that we think Dr. Churchill ought to have included some account of the management of pregnancy, and of its diseases—a subject much more strictly belonging to a treatise on midwifery than the disorders of menstruation, to which he has devoted a long chapter. We must also complain of the meagreness of the index; although we are ready to admit, in extenuation, that a copious index, however useful to the reader, is a most tedious and ungrateful addition to the toils of authorship.

MEDICAL GAZETTE.

Friday, April 14, 1843.

“Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”

CICERO.

MEDICAL EDUCATION.

THE Abbé Sieges, it is said, carried in his pocket several plans of constitutions duly matured, and ready to be produced and acted upon at a moment's warning; and such a councillor must have been useful, and the commodity he possessed must have had much chance of being in request, at a time when new monarchies and republics were being formed to supply the place of those overthrown by the daring genius of Napoleon. Very few indeed, however, have been the occasions when opportunities for constructing such fabrics have arisen, and still fewer the opportunities for a patient and long-continued trial of their working qualities. The adoption of new systems is

generally slow and almost imperceptible. As old things become unfit for present purposes, new ones gradually take their place, but this is done only by degrees; the old usages become first unfit, then burdensome, and lastly intolerable, and those who perceive existing evils are seldom permitted to see the full effects of their labours for their removal. But when this ordinary course of change is departed from, when the agitating and destructive energies have wrought with such unusual force that remodelling and reconstruction have become absolutely necessary for carrying on the daily business of life, the new machinery has rarely indeed been found to answer the intended purpose, and the defeated minority has either gathered strength to reproduce much of the old form, or at least greatly to impede the working of the new. When reformers of the destructive class have succeeded in hurrying on their gigantic experiments, their full trial has nearly always given occasion to exhibit their inefficiency. The mistakes of Calvin had time to exhibit themselves during his life-time, and to convince the world that the religious tyranny of Geneva was no more fitted for civil government than the abominations which it had cast out: so also the despotic power which enabled Cromwell to try his well-meant experiments in England, gave full proof to the world of their entire failure. What wonder, then, if studious and thinking men, either steadily resist all novelty as pernicious, and all change as perilous, or lapse into a state of quietism and indifference more provoking to the ardent reformer than more determined resistance? Though these are times of remarkable change, this is not a country in which a new plan can be universally approved nor quickly adopted, and the reformer who loses his rest in planning, and his temper in urging any favourite

scheme for making mankind happy, will wear out his life before he sees the experiment tried.

Most men who, in after life, find their powers and acquirements unequal to their desires, complain bitterly of the defects in their education; and from this weakness the greatest and best of men, men at whose deeds the world admires, are not exempt, any more than those who have just enough of energy to attempt great things, or just enough of intelligence to perceive their deficiency; and those who are doomed to listen to such complaints are seldom reasonable enough to see, or faithful enough to acknowledge, that the neglect of opportunities that might have been enjoyed has been more in fault than their actual deficiency. It is especially when men who have risen to considerable eminence complain of their own disadvantages, and strive eagerly to remedy this defect in those who are to come after them, that the suggestion arises—How, then, do you hold your present position? Either your own opportunities have been great, and you have but reaped the advantages naturally to be expected from them, or your diligence, perseverance, or more brilliant qualities, have surmounted real disadvantages. From such good qualities, happy results may fairly be expected, in spite of the very greatest disadvantages.

The last writer of eminence on medical education seems to stand very much in this position. Beginning life in a situation which experience proves to be more than most others conducive to mediocrity, he is the favoured medical councillor of his sovereign, the medical chancellor of England, and is exercising a wide and beneficial influence on the sanitary condition of his country; and it may fairly be left to his own candour to determine whether this eminent position be the result of ex-

isting medical institutions, or of such faculties as, if well exerted, could not fail of raising their possessor to eminence. No one who has read the second letter of Sir James Clark to the Home Secretary can fail to agree with the writer on the extreme desirableness of an extended course of philosophical education, nor to deplore the lamentable deficiencies in the most common requirements of a gentleman, observed in candidates for licenses to practise, which their professional acquirements make it impossible to withhold from them.

Nor can any very reasonable objection be found against the kind or amount of preliminary education suggested as a remedy for these deficiencies.

The principal doubt that arises will be as to their practicability; not that they are unattainable by the few, but by the many. The worthy Baronet's hope that this may cease to be an obstacle, that the many may become few, is indeed benevolent, *faxit Deus!* but will it be realized, and when? Are these Deuteronomic blessings for us or for our children? How long will it be before parents will cease to condemn their sons to the practice of physic, and the public to countless doctors. The London Directory gives the names and addresses of 320 physicians, 1400 surgeons, 10 apothecaries who are not surgeons, and 600 chemists and druggists, who, it is to be feared, are both *tant soit peu*, making a gross total of 2330. Do we find much thinning out of the young plants, hardy and hot-house, raised every year at those goodly *pepinieres*, the medical schools; and do those transplanted to different parts of the kingdom seem to thrive? It is to be feared not.

There is a great fact which must not be lost sight of in legislating for the medical profession. We have

to lay up a good general education, that we may be capable of profitably learning a science, and we learn the science of medicine that we may live by practising the art. Now this, in spite of all legislation and all theory, divides the members of the profession into two great natural orders; those namely, who can afford to wait, and those who cannot. To one or other of these two groups all who enter the profession belong. But if every existing chartered or corporate body were at once abolished, these two classes of persons would have to be cared for. And the existing corporate bodies, however faulty in their principles or details, do at present care for them, and legislate for them more or less efficiently. The first class, those who can afford to wait, living on their capital and private resources until they can realize a professional income, are cared for by the College of Physicians. This class, and the body which rules it, gives but little trouble to the state—its police is internal rather than external, private rather than public. In its earliest days it undertook to secure the learning, the "*mores*," even the piety of its members, and though empowered also to act on the offensive and defensive against all unqualified attempts on the health of the public it soon gave up this disagreeable duty, and merely insisted that the conduct of its members, while unemployed, should be inoffensive, and when employed honest and of good report. The Censors left off emptying the gallipots of unprincipled apothecaries into the kennel, and gave their dignified attention to the new office of guarding their College from the admission of the unorthodox, and the correction of the contumacious members.

The apothecaries practising without license from the College of Physicians soon required a very different kind of police; and the charter of the Apothe-

caries' Company was intended to supply that want. Entrusted with the power of granting licenses to practise, the company soon conferred their privileges on a very numerous body, and occupied itself diligently in fencing the approaches and guarding the outworks of medicine. For internal police they had no time, no taste, or no powers: whoever obtains their license may practise where he likes and how he likes—may get a high price for his skill and acquirements, or may compete with the neighbouring grocer in the selection and display of his wares.

FELLOWES' CLINICAL PRIZE REPORTS.

By ALFRED J. TAPSON.
University College Hospital, 1842.

[Continued from p. 940 of the preceding volume.]

CASE IX.—*Erysipelas of the face, followed by scarlatina and an abundant minute vesicular eruption; cured by aperients, antimonials, &c.*

THOMAS BATEMAN, ætat. 32, admitted April 30th, 1842, under Dr. Williams. A large stout man of a full habit of body, and sanguine temperament; is married, but has no children; is a footman, and has been in the habit of drinking about three quarts of beer daily, often more, sometimes getting drunk. Has no hereditary predisposition to disease; his general health has been good. About fourteen years since he had a severe attack of brain fever, and has ever since been subject to giddiness on stooping, &c. Four years ago he had an attack of rheumatism in the right knee which laid him up for two months; has had a cough for the last three or four months, and says he has got much thinner, but he still has plenty of fat.

The *present attack* commenced two days since; he had been walking several miles and got very hot, and returned home in the evening when it was cold, and drank three glasses of rum and water, which he is not in the habit of drinking at all. Soon after he arrived home he felt shivered very much, and the left side of the lower jaw felt painful, and the teeth ached; swelling speedily came on about the angle of the jaw, and by the next morning had extended all up that side of the face, partly closing the left eye; the swelling was red and shining, there were no vesicles on it; at this time he felt very sick,

and vomited whatever he took; he, however, managed to keep down one dose of pills which purged him freely; the vomiting continued all the day; he was very hot and perspired abundantly.

Present symptoms.—The swelling has now extended to the right side of the face and nose; it does not pass up over the scalp, but the redness terminates by an abrupt margin near the scalp; the swelling is hard, red, and shining, not very painful; but the face feels stiff; the skin is hot; pulse about 100, and full; has a slight headache; no difficulty of breathing; the tongue is furred a good deal, and he has a bad taste in the mouth, and is thirsty; urine scanty, and high coloured.

Foveatur facies aquâ calidâ frequenter.
Low diet.

R. Ext. Col. Comp. gr. x. omni nocte sumend.

R. Antimon. Potassio Tart. gr. ʒ. ; Acidi Hydrocyan. dilut. ℥v. ; Sodæ Tart. ʒss. ; Aqua, fʒi. M. f. haust. ter die sumend.

May 1st.—The swelling has increased in the lower part of the face, and has extended down into the neck; it itches very much; the vomiting has ceased; there is no delirium.

2d.—Swelling much the same; bowels confined.

R. Haust. Sennæ Comp. cras mane.

3d.—The swelling is very much reduced, and he feels much easier. The urine increased in quantity, and paler. Towards the afternoon shivering came on with slight soreness and dryness of the throat, cough, and a little mucous expectoration; the shivering continued for some hours, and in the evening a slight redness was observed on the chest and side, and the urine was again scanty and high coloured.

4th.—The swelling of the face and neck is almost gone, and the cuticle is desquamating all over the face. The redness that commenced yesterday is gradually extending over the trunk and extremities: he is still shivered at times, and has some headache; the bowels are open; the urine high coloured, not albuminous; the tongue is much cleaner than it was, and there is less thirst.

5th.—During the night the skin has become of a bright scarlet all over the body; the redness is not like that of erythema, being in points, and not diffused; it is removed by pressure, but quickly returns; the skin feels hot and rough to the touch, and the roughness is found on close examination to depend on an umber of minute distinct vesicles containing a turbid serum (as was ascertained by puncturing some of

the larger of them); they are scattered very thickly all over the surface of the trunk, and also at the bend of the elbows and in the groins. He complains of a "smarting kind of soreness" all over the body, but especially at the joints, and the palms of the hands are rather hot and tender; there is no swelling except about the feet and ankles, which are slightly oedematous, and pit on pressure. The uvula, fauces, and tonsils, are red and sore, and the tongue is now morbidly clean, very red and rather dry; the surface of it is totally smooth, and the papillæ are not enlarged, or only very slightly so indeed; there is no running at the eyes and nose; pulse 86, regular, &c.; bowels open; urine free, lighter coloured than it was, sp. grav. 1020, not albuminous by heat and nitric acid.

6th.—The redness is faded considerably, and most of the vesicles have disappeared, and the cuticle is beginning to desquamate at the bending of the joints, also in the hollow of the back and over the shoulder; it comes off in large flakes, and is not therefore merely the desquamation of the vesicles. The flakes when examined by the microscope are seen to be composed of a single layer of the scales of the epidermis, each more or less regularly hexagonal in form. The skin is still rather above the natural temperature; the tongue and fauces are less red, and more comfortable; the thirst less. On the shins there is a deeper redness, which is not removed by pressure, and indeed, in those parts of the body where the redness is removed by pressure, the skin is observed to have a yellow tinge, depending probably on some alteration of the colouring matter of the blood. The eyes feel weak, and there is a little running from them; there is not much swelling of the ankles; urine still high coloured, but not albuminous.

7th.—Much better altogether; the skin is desquamating generally over the surface of the body, and there is very little redness remaining, excepting on the shins; the throat is not sore now; tongue still red; appetite returning, no running at the eyes or nose, pulse 85; bowels open; urine abundant, less high coloured; reaction neutral, sp. grav. 1020, not albuminous.

Omittatur Mistura. Middle diet.

9th.—Nearly convalescent; feels stronger; appetite good; tongue clean and natural; no thirst; the redness is almost gone from the shins. Bowels open; urine plentiful: on heating it, and then adding nitric acid, slight cloudiness is produced, but scarcely enough to prove the existence of albumen.

10th.—The swelling is quite gone from the ankles, and the colour of the legs is almost natural; desquamation is still pro-

ceeding; urine natural; reaction acid; sp. gr. 1018, not at all albuminous.

11th.—Urine not albuminous.

13th.—Slight desquamation taking place from the legs. Urine not albuminous.

15th.—Discharged cured.

REMARKS.—After reading the preceding report, it is pretty apparent that he came into the hospital with erysipelas, and that when he was recovering from this he was attacked by scarlatina. Both the diseases proved slight, and he was discharged cured in a little more than a fortnight from the time of his admission.

The symptoms under which he laboured on his admission were so obviously those of erysipelas, that no doubt could be entertained of the nature of his disease. 1st, The characters of the swelling itself—its red, smooth, and shining surface, bounded by an abrupt margin, and its tendency to spread. 2d, The symptoms attendant on its development—the shivering, quick pulse, and gastric disturbance, amounting to vomiting, which lasted till the swelling had attained almost its full extent; and also, 3d, The mode of its departure—a gradual subsidence of the swelling, followed by desquamation of the cuticle. Again, the subject of the attack, and the circumstances preceding its appearance—the patient being a man of a full habit of body, in the habit of drinking freely, and whose kidneys, therefore, may be imagined to be somewhat impaired in function, and unable to carry off any noxious or superfluous matters when the excretion by the skin was arrested, as probably it was here, by the exposure to cold after active exertion, and then the fact of his drinking several glasses of rum and water, a liquid to which he is not accustomed—all of these would favour the occurrence of such an attack, especially as it appears his health has been suffering ever since Christmas; and the wonder is, that as the part attacked was the face, and he had previously had brain-fever, and determination of blood to the head since, that there were no cerebral symptoms produced.

The treatment indicated was to set the secretions free, especially those of the bowels and skin, and this was effected by a combination of aperients and antimonial salines, and warm fomentations were applied to the part to soothe the irritation and promote perspiration. The cause of the erysipelas was apparently not of a specific nature, and the attack was probably produced by the combination of circumstances above mentioned.

The prognosis was favourable from the attack not being very severe, and the constitution naturally good.

Next, with respect to the second attack of feverishness and the accompanying eruption,

there are a few points deserving attention. First, as to the *diagnosis*: if we look merely at the general features of the case, we shall have very little hesitation in pronouncing it to be scarlatina simplex: it commenced with feverishness, pain in the head, slight sore-throat, scanty high-coloured urine, &c., followed by a rash, which at first was of a pale red colour, spreading over the whole body by the third day, and becoming of a scarlet or crimson colour, and attended with smarting—the redness beginning to fade on the fourth day, and ending in universal desquamation of the cuticle by the sixth or seventh day. The only symptom of scarlatina that was not well marked, was, that the papillæ of the tongue were scarcely, if at all, enlarged, though the tongue was very red. This might be partly due to the age of the individual, rendering the tongue less readily affected than it is at the age at which we most commonly see scarlatina; and it is certain that in children the papillæ of the tongue are more readily affected by other causes than in adults; and also the enlargement of the papillæ is less marked in scarlatina simplex than in scarlatina anginosa.

In addition, however, to the usual symptoms of scarlatina, there was, in this case, a remarkably abundant vesicular eruption at the time when the rash was most vivid, and this caused a little perplexity as to whether the disease really was scarlatina; but we know that a vesicular eruption is not a very uncommon occurrence in scarlatina, and in some other fevers, and the fact of its being so much more abundant here than usual cannot be of much importance; and besides, the redness was quite characteristic of scarlatina, both in intensity and in tint; and also it was in points which distinguish it from erythema læve, the only other disease with which it was at all likely to be confounded. Had the vesicular eruption occurred with less redness it might have been called miliary fever.

The indications of treatment were much the same as for the erysipelas, and the same remedies were continued—and the early disappearance of the vesicles and redness, and the rapid decline of all the symptoms, confirmed the idea that had been held respecting the nature of the disease, viz. that it was scarlatina simplex, accompanied by an accidental miliary eruption.

The cause of the attack is not evident; but considering that scarlatina was prevalent at the time, and that he had only been in the hospital three days before the symptoms of it came on, we conclude that notwithstanding he is not aware of having been near any one with scarlatina, he must have been exposed to it in some way or other, and that recently before his admission. It may be mentioned that he had never had scar-

latina before. With regard to the urine, it is stated by Chevreul that this generally contains albumen at the period of the desquamation of the cuticle in scarlatina; in this case the urine was carefully examined every day about this time, and on no occasion was there any decided evidence of albumen in it, and there was only a slight amount of anasarca. The age of the patient was probably the chief cause of this, for Dr. Prout remarks that "anasarca and albuminous urine are much more rare as a sequela of scarlet fever in adults than in children, and the severity is in the inverse ratio of the eruptive fever and sore-throat." As none of the sequelæ had appeared before he left the hospital, it is most likely that he will escape them.

ON THE SPECIAL FUNCTION OF THE SKIN.

BY R. WILLIS, M.D.

THE purpose which is answered in the animal economy by the function of the skin has not yet been precisely indicated by physiologists. It is universally acknowledged of immense importance to the health; but no one has said how or wherefore it is so. The chemical analysis of the sweat is acknowledged to throw no light on the ends for which it exists; and the principal matter excreted from the skin is water: sweat contains about 99 per cent of this fluid. The author of this paper considers the water as the essential excretion; not, however, in the usual sense in which the word excretion is used, nor yet as a means of regulating or reducing temperature. In the means which nature takes to preserve the lower animals from the effects of loss of heat by sending them into the world ready clothed, and in the uniformity with which man contrives to clothe himself over so large a portion of the earth's surface, he sees that the object is generally to economise heat, not to dissipate it. He says there is even something like an absurdity involved in the invocation of a system to cool the body, seeing that one great business of life, in all the temperate and cold countries of the world, is to guard against the loss of heat. Heat is lost, indeed, to a great extent, in converting the product of the sudoriparous glands into vapour; but the loss here was unavoidable; it is not the end. In spite of all the sudoriparous glands can do, also, the experiments of Delaroche and Berger have shown that the heat of the body rises considerably above the standard when exposed to temperatures somewhat higher than itself. In chambers heated to 120° and 130° Fahr. the tempera-

ture of animals rises, within an hour, to from 11° to 16° above what it had been before, and life is destroyed. And then the suppression of the cutaneous exhalation is by no means followed by a rise in the temperature of the body. In general dropsies, which are attended with a remarkable diminution of this secretion, an icy coldness usually pervades both the body and the limbs. A great fall in the animal temperature was likewise found by Fourcault and Becquerel and Breschet to be the effect of covering the body with a varnish impervious to perspiration; and so serious was the general disturbance of the functions in these circumstances, that death sometimes ensued in the course of from three to four hours. Delaroche and Berger had also found that confinement in an atmosphere of no higher temperature than the body of an animal, but saturated with moisture, was rapidly fatal; animals scarcely resisted such an atmosphere for an hour before they were reduced to extremity. Whatever prevents the skin from performing its function, *i. e.* from throwing off a little water, is very speedily fatal.

How may this effect be produced? How does it happen that health and even life can be so immediately dependent, as they certainly are, on the elimination of some thirty-three ounces from the general surface of the body in the course of the twenty-four hours? To this the author answers,—by securing the conditions which are necessary for the endosmotic transference between arteries and veins of the fluids that minister to nutrition and vital endowment.

It is admitted by physiologists that the blood, while still contained within its conducting channels, is inert with reference to the body, no particle of which it can either nourish or vivify until that portion of it which has been denominated the *plasma* has transuded from the vessels and come into immediate contact with the particle that is to be nourished and vivified: but no physiologist has yet pointed out the efficient cause of these tendencies of the plasma, first, to transude through the wall of its efferent vessels, and secondly, to find its way back again into the afferent conduits. The explanation given by the author is that, in consequence of the out-going current of blood circulating over the entire superficies of the body perpetually losing a quantity of water by the action of the sudoriparous glands, the blood in the returning channels has thereby become more dense and inspissated, and is brought into the condition for absorbing, by endosmosis, the fluid perpetually exuding from the arteries, which are constantly kept on the stretch by the injecting force of the heart.

Repeated experiment has demonstrated the fact that the blood in the veins is of

somewhat greater density than that in the arteries. If the specific gravity of arterial blood be allowed to be 1.050, that of venous blood in the mean will be 1.503.

In an appendix to the paper, the author points out a few of the practical applications of which the above-mentioned theory is susceptible. Interference with the function of the skin, and principally through the agency of cold, he observes, is the admitted cause of the greater number of acute diseases to which mankind, in the temperate regions of the globe, are subject. He who is said to have suffered a chill, has, in fact, suffered a derangement or suppression of the secreting action of his skin, a process which is altogether indispensable to the continuance of life; and a disturbance of the general health follows as a necessary consequence.

Animals exposed to the continued action of a hot dry atmosphere die from exhaustion; but when subjected to the effects of a moist atmosphere of a temperature not higher than their own, they perish by the same cause as those which die from covering the body with an impervious glaze; for, in both cases, the conditions required for the access of oxidized, and the removal of deoxidized plasma, are wanting, and life necessarily ceases. The atmosphere of unhealthy tropical climates differs but little from the vapour-bath at a temperature of between 80° and 90° Fahr.; and the dew point in those countries, as for example on the western coast of Africa, never ranges lower than three or four degrees, nay, is sometimes only a single degree, below the temperature of the air. Placed in an atmosphere so nearly saturated with water, and of such a temperature, man is on the verge of conditions that are incompatible with his existence: conditions which may easily be induced by exposure to fatigue, to the burning sun, or other causes which excite the skin while the circumstances necessary to the exercise of its natural function are wanting. The terms *Miasma* and *Malaria* may, according to the author, be regarded as almost synonymous with air at the temperature of from 75° to 85° Fahr., and nearly saturated with moisture.

The secretion of the skin otherwise suppressed is attended with no less fatal consequences. What kills a patient within the first 48 hours of a bad attack of scarlet fever? The autopsy shows nothing amiss. He dies undoubtedly from the complete suppression of the function of the skin. Restore this and he will do well; all the stimulants in the world will not rouse him if the function of his skin be not restored.—*Proceedings of the Royal Society*, March 2d and 9th.

THE TWENTY-SIXTH REPORT OF
THE AYR, NEWTON, AND WALLACE-
TOWN DISPENSARY,
1843.

Now that there is a government commission appointed to inquire into the operation of the Poor Law of Scotland, all matters connected with the poor are of course exciting at present a high degree of interest in the country, and we trust that the commissioners will not only direct especial attention to the state of the medical charities presently in active operation, but that they will devise some means of more perfectly providing for the sick poor in rural districts as well as towns. The excellent and interesting report now before us proves in an eminent degree the necessity there exists for great alterations being made with a view to ameliorate the condition of the sick poor. It appears that this Institution extends its beneficial operations over a locality which comprises a population of 14,285. "To keep up," says the reporter, "the dispensary, £95 is paid annually by 150 subscribers, which is an average payment of 12s. 8d. each!"

If the only medical charity available (we are aware that a Fever Hospital is in progress of erection) to the destitute sick, of a population of 14,285, can be kept up by an annual expenditure of £95, we should have declared ourselves utterly unable to guess by what even *canny* management an efficient Institution for such a district could be kept up with means so apparently insignificant, had we not observed some time ago, in a report furnished to the Poor-Law Commissioners by Dr. Sym, of Ayr, the following statements:—"The poor are humanely attended, and their diseases skilfully treated, by five dispensary surgeons, who divide the town into districts and visit the patients in their own houses;" "the expenses are defrayed by an annual subscription" (£95!) "The surgeons receive a trifling sum, (£5 annually, each, we believe) not as a remuneration for their services, but as a token of gratitude for the sacrifices they make for the good of the community."* What, we would ask, would a surgeon of any of our English Unions think, if he were to receive the gratifying assurance that he might calculate on £5 after a year's most toilsome and disagreeable labour! which he is most benevolently requested by no means to look upon as a remuneration for his services, but as a token of gratitude for the sacrifices he has made for the good of the community?"!!!

We can scarcely suppress a smile when

* Vide Sanitary Reports, Scotland, Ayr, by Dr. Sym, p. 236.

the talented reporter, in the face of this, can only summon up courage to enable him "to venture to express a hope that the Commissioners recently appointed to enquire into the state of the poor in Scotland will take into consideration the propriety of supporting medical charities by assessment."*

MEDICAL REFORM.

To the Editor of the Medical Gazette.

SIR,

As it appears to be the intention of the government to bring forward some measure on medical reform, and believing it to be their anxious desire to be guided by the soundest judgment and discretion, permit me to state, through the medium of your columns, those results at which long experience has enabled me to arrive on this important question.

No reasonable being can suppose or expect that the government should so interfere with any other view than that of securing the greatest amount of public security and of public good.

Called upon, as it now is, to interpose its influence, by the obstinate refusal of all reasonable concessions on the one hand, and, on the other, by extravagant demands, it seems to me important to direct attention to the following facts.

Although it is imperatively necessary to establish the most efficient forms of examination, so as to secure fitly educated men for so responsible a station in life as that which all medical practitioners necessarily occupy, I am quite satisfied that the plans hitherto adopted have totally escaped that attention which they so seriously demand from the public at large.

We must all feel, that a diploma granted upon oral or written examination, on "*professional qualification or power*" can afford no real safeguard to the public, nor any evidence of the candidate's fitness to practise in any branch of his profession. I declare that a diploma granted upon such evidence conveys to the public mind a fallacious and dangerous claim to confidence and skill.

Let me illustrate this assertion by evidence, in its most glaring shape. Is it not the universally received opinion of mankind, when they see the title of "Doctor," or "M.D." appended to a name, that they implicitly, yet ignorantly, conclude this man to possess superior skill, and to carry with him a proportionate degree of security by his attendance? Can any thing be more deceptive or more dangerous? I assert, and defy

contradiction, that there are many members of the College of Physicians, and not a few of these backed by an Oxford or Cambridge Degree, totally devoid of all practical knowledge, and whose minds are unfitted to acquire it. I say not this with any feeling of intentional disrespect; my only object is to show the naked truth, and, in doing so, to prove the absurdity of those artificial distinctions which at present exist, and to point out that change which I believe alone capable of remedying the evils complained of, so far as it may be practicable to do so.

It seems that the government is now pausing whilst the Colleges of Physicians and Surgeons reconcile some conflicting opinions; but if Parliament seriously keep in view the public welfare, and legislate, as it is in duty bound to do, for the promotion of *this one great object*, I deem it absolutely necessary to throw overboard the entire corporate and chartered privileges of the Colleges of Physicians and Surgeons, and of the Apothecaries' Company also.

Having already offered indisputable evidence against the present system of examination affording to the public a greater extent of protection through the College of Physicians itself than through either of the other two licensing bodies, I maintain that if one Faculty or College be instituted, such a system may be devised as will accomplish every useful and necessary purpose. I will leave the form of appointment of this one Faculty for the present untouched; I simply throw out the suggestion.

The examinations, academical and professional, should be the same for all candidates; but as the profession naturally subdivides itself into three separate states, viz. the physician, the consulting surgeon, and the general practitioner, every candidate, after his examination, should be required to take out his diploma for that branch of his profession which he intends to pursue. Each of the three branches should have the option to practise midwifery, and I would leave the public to determine every other point of respective right. I am positively convinced that no legislation can ever extinguish or amalgamate the three distinct divisions before stated.

Would Sir Benjamin Brodie attend a case of fever? Dr. Chambers a fractured limb? or would the public entirely repose their confidence in the hands of the most able general practitioner? or, indeed, would the practitioner himself desire it? Most certainly not. A plan might even be adopted by which the powers of this newly constituted body should be strictly confined to examination, and, having so satisfied itself of the candidate's due qualification, should remit him with its certificate to that body under whose diploma it is his intention to act.

* We should be glad to receive the other communications alluded to by our correspondent.

The fees or exclusive rights of each of the three present corporations would then remain intact and perfect. As, however, unforeseen events and circumstances often blast the brightest prospects, or cause the dazzling glare of unlimited success and wealth to fall where least expected, I would reserve to every man, at any subsequent period of life, the power to exchange his diploma, for one of higher or lower degree, upon the production of such certificates of character, conduct, and motives, as the faculty should deem satisfactory. Hence the great utility of the examination being the same for all three departments: and as there are unquestionably many physicians and surgeons, who would, at this time, gladly avail themselves of pharmaceutical practice, if the Apothecaries' act did not prohibit them; and as there are some few general practitioners, who, being fully qualified by experience and position, might choose to take out their diploma as physicians, I would make due provision for these purposes, on similar testimony to that required in cases of change of degrees.

It is desirable to put an end to all dissension, which I believe such a measure as I advocate is fully adequate to accomplish.

It does not destroy any peculiar powers contended for, either by one body or another. It does destroy all unjust claims of distinction between the physician, the surgeon, and the general practitioner. It provides for the public safety in a greater degree than has hitherto been done. It leaves all men free to act as they please for the future; the possession of which power deprives every member of all ground of complaint, and at the same moment extinguishes every desire for that change after which the mal-content has been brawling during the greater portion of his life.

The same law ought to govern the three kingdoms, and one Pharmacopœia ought to be adopted. Every man practising without due license ought to be prosecuted by the licensing body; and with this provision, quacks and quackery may be safely left as sources of justifiable public amusement.

I am, sir,
Your obedient servant,
NEMO.

THE PHOSPHATES IN POTATOES.

To the Editor of the Medical Gazette.

SIR,

IN my last lecture, in the number of the MEDICAL GAZETTE for March 31, an error occurred, which has been alluded to by a correspondent in to-day's number. In the manuscript lecture "three" ounces of pota-

toes were inserted instead of four; so that, in page 16, line 52 in the first column, for *three* ounces, *four* should be substituted.

The quantity of phosphates in potatoes I took from the table given in page 78 of the very interesting and talented work of Dr. Bence Jones, "On Gravel, Calculus, and Gout," 1842; where, on the authority of Liebig's work, he has stated 49.1 ashes to be present in 1000 grains of potatoes, equal to 23.56 in the ounce of 480 grains. On referring to Liebig's work, I find that Dr. Jones misplaced the decimal point; so that, instead of 49.1, the quantity is really 4.91 grains = 2.356 in an ounce, and reducing the quantity of phosphates in my "imaginary" meal to rather more than 30 grains. I need hardly say, this error does not affect the argument.

In page 14, col. 1, line 7, an absurd error escaped correction: instead of "polarized light," it stands in the text "pulverized light."

I should have corrected these errata in a foot-note to the next lecture, had not they been noticed in the present number.

I remain, sir,
Your obedient servant,
GOLDING BIRD.

14, Myddelton Square,
April 7, 1843.

TREATMENT OF INSANITY.

THE Visitors, in complying with the annual custom of presenting a Report of the Asylum to the public, have still the satisfaction of referring to the successful treatment pursued in it, and to the increased domestic comfort which has been insured to the patients.

The system they reported last year as under trial, of introducing a limited number of students of each sex to an association with the patients of both sexes, and of employing females more freely to assist in the attendance upon the male patients, has been persevered in throughout the year, and has fully answered the expectations entertained. The patients being under the immediate direction of educated persons, instead of being left to the care of servants, have been manifestly more comfortable, and that state of irritation and disquietude, so often observed amongst the inmates of an Asylum, has been so generally removed, that the resident Physician has formed the first-class patients of both sexes, together with the students and the members of his own family, into one domestic party, and they daily assemble for meals and for amusement, in one or other of their respective apartments.

It is perhaps needless to allude to the effect of this friendly and domestic union upon the minds of the patients; the advantages are

manifest and numerous; but its influence in removing much of the pain of restricted liberty, and in shewing the patient, that though controlled by, he is still the companion of, his medical director, is worth an especial notice.

All mechanical restrictions upon the persons of the patients have continued to be disused during this year: the state of the house has, in its quietness and tranquillity, warranted this; and though occasional violence on the part of patients has, as formerly, occurred, a more judicious appeal to the moral instead of the physical powers of the attendants—a removal of the excited from the society of his comrades—or, a more complete seclusion in a well guarded chamber—have been found to subdue the violence, when mechanically confining the limbs might only have increased the irritation. But besides this, in the disuse of mechanical restraint *altogether*, the feelings of those whose quiet deportment would always have secured them from its application to their own persons, are saved the offence of witnessing its application to their less tranquil companions.

The employment of the patients has been very much increased. A resident tailor and a shoemaker have been added to the Establishment, and those of the patients who are, either from previous acquaintance with these trades, or from a desire to learn them, inclined to undertake work in them, are encouraged to do so; but our medical officers encourage more generally those employments which lead the patients from a sedentary state, and which will engage them in the open air; and for this purpose the greater attention is still given to the work of the garden.

To the accustomed round of balls, evening parties, &c. our Superintendent has for some time past added the Mainzerian system of singing for his patients, and of all the amusements calculated for a Lunatic Asylum, it is perhaps one of the best that could be devised. It may not be the most perfect mode of teaching *the art*—it may not be so essential to the individuals whose station in society, and whose means, may have enabled them to cultivate music on a more extended scale—but, to the less favoured, and the most numerous class of patients in the Asylum, it is the greatest treat; and no evening in the week is looked forward to with so much pleasure as the “singing” one. It is valuable, not as an *amusement* only, but as an *occupation*—for the patient has something to do—something to prepare himself for—and many an hour in the week, which, perhaps, might have been painfully past, glides pleasantly away as he cons over his part for the ensuing concert. But this practice calls out also the kinder feelings of those patients,

to whom such a mode of singing is less acceptable for their own amusement; it leads the better classes to enter into it, and to encourage it, because it gives delight to the poorer and less informed; and thus the strongest feeling in insanity—*selfishness*—is in a material degree subdued and corrected in their minds.

This gradual advance which has been made in the improved treatment of the insane has necessarily led to an improved provision for them in the Asylum. For those of the first and second classes especially the accommodations have been made nearly resembling their homes: the wards of the Asylum have been assimilated to domestic dwellings, and the strangeness of a place of confinement as far as possible changed into the appearance of comfort and cheerfulness. This improvement in the treatment of the insane, and the quietness which ensues from it, together with that system of individual confidence, in which this Asylum ventures to claim a peculiar success, produce important consequences in point of economy. For a very great increase of pauper patients has been accommodated with but little expense in building, by the discovery that it is no longer necessary, as was formerly supposed, to have a separate sleeping cell for each patient, but that a proportion (at present, nearly *one-half*;) may safely be placed in dormitories containing four to sixteen beds, and in which they pass the night without even the presence of an attendant. This is not a saving which affects the weekly amount of charge for maintenance, but it much lessens the other head of charges, which must else have been thrown on the county.—*Report, Gloucester Lunatic Asylum.*

PAYMENT TO MEDICAL OFFICERS OF UNIONS.

To the Editor of the Medical Gazette.

SIR,

IN March 1842, I addressed a letter to the surgeons of the London Unions, who had called on me as the then President, and on the Vice-Presidents of the Royal College of Surgeons, stating my views respecting the medical order of the Poor Law Commissioners of the 12th of that month, regulating the payments to be made to the medical officers of unions for *extraordinary services*.—which letter you were pleased to
You also thought it right to make
second letter I addressed to the
men, on the subject of an
hoped I had
State and the

The fees or exclusive rights of each of the three present corporations would then remain intact and perfect. As, however, unforeseen events and circumstances often blast the brightest prospects, or cause the dazzling glare of unlimited success and wealth to fall where least expected, I would reserve to every man, at any subsequent period of life, the power to exchange his diploma, for one of higher or lower degree, upon the production of such certificates of character, conduct, and motives, as the faculty should deem satisfactory. Hence the great utility of the examination being the same for all three departments: and as there are unquestionably many physicians and surgeons, who would, at this time, gladly avail themselves of pharmaceutical practice, if the Apothecaries' act did not prohibit them; and as there are some few general practitioners, who, being fully qualified by experience and position, might choose to take out their diploma as physicians, I would make due provision for these purposes, on similar testimony to that required in cases of change of degrees.

It is desirable to put an end to all dissension, which I believe such a measure as I advocate is fully adequate to accomplish.

It does not destroy any peculiar powers contended for, either by one body or another. THE PHOSPHATES IN POTATOES.

To the Editor of the Medical Gazette.

SIR,

IN my last lecture, in the number of the *MEDICAL GAZETTE* for March 31, an error occurred, which has been alluded to by a correspondent in to-day's number. In the manuscript lecture "three" ounces of pota-

toes were inserted instead of four; so that, in page 16, line 52 in the first column, for *three* ounces, *four* should be substituted.

The quantity of phosphates in potatoes I took from the table given in page 78 of the very interesting and talented work of Dr. Bence Jones, "On Gravel, Calculus, and Gout," 1842; where, on the authority of Liebig's work, he has stated 49.1 ashes to be present in 1000 grains of potatoes, equal to 23.56 in the ounce of 480 grains. On referring to Liebig's work, I find that Dr. Jones misplaced the decimal point; so that, instead of 49.1, the quantity is really 4.91 grains = 2.356 in an ounce, and reducing the quantity of phosphates in my "imaginary" meal to rather more than 30 grains. I need hardly say, this error does not affect the argument.

In page 14, col. 1, line 7, an absurd error escaped correction: instead of "polarized light," it stands in the text "pulverized light."

I should have corrected these errata in a foot-note to the next lecture, had not they been noticed in the present number.

I remain, sir,
Your obedient servant,
GOLDING BIRD.

TREATMENT OF INSANITY.

THE Visitors, in complying with the annual custom of presenting a Report of the Asylum to the public, have still the satisfaction of referring to the successful treatment pursued in it, and to the increased domestic comfort which has been insured to the patients.

The system they reported last year as under trial, of introducing a limited number of students of each sex to an association with the patients of both sexes, and of employing females more freely to assist in the attendance upon the male patients, has been persevered in throughout the year, and has fully answered the expectations entertained. The patients being under the immediate direction of educated persons, instead of being left to the care of servants, have been manifestly more comfortable, and that state of irritation and disquietude, so often observed amongst the inmates of an Asylum, has been so generally removed, that the resident Physician has formed the first-class patients of both sexes, together with the students and the members of his own family, into one domestic party, and they daily assemble for meals and for amusement, in one or other of their respective apartments.

It is perhaps needless to allude to the effect of this friendly and domestic union upon the minds of the patients; the advantages are

manifest and numerous; but its influence in removing much of the pain of restricted liberty, and in shewing the patient, that though controlled by, he is still the companion of, his medical director, is worth an especial notice.

All mechanical restrictions upon the persons of the patients have continued to be disused during this year: the state of the house has, in its quietness and tranquillity, warranted this; and though occasional violence on the part of patients has, as formerly, occurred, a more judicious appeal to the moral instead of the physical powers of the attendants—a removal of the excited from the society of his comrades—or, a more complete seclusion in a well guarded chamber—have been found to subdue the violence, when mechanically confining the limbs might only have increased the irritation. But besides this, in the disuse of mechanical restraint *altogether*, the feelings of those whose quiet deportment would always have secured them from its application to their own persons, are saved the offence of witnessing its application to their less tranquil companions.

The employment of the patients has been very much increased. A resident tailor and a shoemaker have been added to the Establishment, and those of the patients who are, either from previous acquaintance with these trades, or from a desire to learn them, inclined to undertake work in them, are encouraged to do so; but our medical officers encourage more generally those employments which lead the patients from a sedentary state, and which will engage them in the open air; and for this purpose the greater attention is still given to the work of the garden.

To the accustomed round of balls, evening parties, &c. our Superintendent has for some time past added the Mainzerian system of singing for his patients, and of all the amusements calculated for a Lunatic Asylum, it is perhaps one of the best that could be devised. It may not be the most perfect mode of teaching *the art*—it may not be so essential to the individuals whose station in society, and whose means, may have enabled them to cultivate music on a more extended scale—but, to the less favoured, and the most numerous class of patients in the Asylum, it is the greatest treat; and no evening in the week is looked forward to with so much pleasure as the “singing” one. It is valuable, not as an *amusement* only, but as an *accupation*—for the patient has something to do—something to prepare himself for—and many an hour in the week, which, perhaps, might have been painfully past, glides pleasantly away as he cons over his part for the ensuing concert. But this practice calls out also the kindler feelings of those patients,

to whom such a mode of singing is less acceptable for their own amusement; it leads the better classes to enter into it, and to encourage it, because it gives delight to the poorer and less informed; and thus the strongest feeling in insanity—*selfishness*—is in a material degree subdued and corrected in their minds.

This gradual advance which has been made in the improved treatment of the insane has necessarily led to an improved provision for them in the Asylum. For those of the first and second classes especially the accommodations have been made nearly resembling their homes: the wards of the Asylum have been assimilated to domestic dwellings, and the strangeness of a place of confinement as far as possible changed into the appearance of comfort and cheerfulness. This improvement in the treatment of the insane, and the quietness which ensues from it, together with that system of individual confidence, in which this Asylum ventures to claim a peculiar success, produce important consequences in point of economy. For a very great increase of pauper patients has been accommodated with but little expense in building, by the discovery that it is no longer necessary, as was formerly supposed, to have a separate sleeping cell for each patient, but that a proportion (at present, nearly *one-half*;) may safely be placed in dormitories containing four to sixteen beds, and in which they pass the night without even the presence of an attendant. This is not a saving which affects the weekly amount of charge for maintenance, but it much lessens the other head of charges, which must else have been thrown on the county.—*Report, Gloucester Lunatic Asylum.*

PAYMENT TO MEDICAL OFFICERS OF UNIONS.

To the Editor of the Medical Gazette.

SIR,

IN March 1842, I addressed a letter to the surgeons of the London Unions, who had called on me as the then President, and on the Vice-Presidents of the Royal College of Surgeons, stating my views respecting the medical order of the Poor Law Commissioners of the 12th of that month, regulating the payments to be made to the medical officers of unions for *extraordinary* services; which letter you were pleased to publish. You also thought it right to make known a second letter I addressed to the same gentlemen, on the subject of an arrangement I hoped I had made with the Secretary of State and the Poor Law Commissioners, with

respect to certain fixed payments for the ordinary services of the medical officers of Unions, and which I was led to apprehend, would have formed a part of the amended Bill about to be laid before Parliament.

The difficulties and alarm, under which the country, and particularly the agricultural part of it, have been for some time labouring, will I fear prevent the accomplishment of this object, which is so much desired by the members of the medical profession, unless the sense of the House of Commons should be strongly expressed upon it. In order to obtain this, it is necessary that a clear and accurate statement of the sufferings of the sick poor should be laid before it, and of the grievances which medical men sustain under the authority (but, I am firmly convinced, against the wishes) of the Poor-Law Commissioners, which prevent their being able to give these unhappy persons that assistance which their state demands and deserves at the hands of their more fortunate neighbours.

Colonel Wood (Middlesex) has moved for such returns (and will move for more if necessary) as will enable him to bring this matter under the consideration of the House of Commons as soon as the amended bill shall be presented. To enable him to do this effectually, a statement must be furnished to him of all the sufferings and grievances above alluded to; and if the members of the medical profession who have suffered, and are suffering, or are aggrieved, shall be pleased to address their statements to me, I will prepare such digest of them as will enable him and the House of Commons to understand this subject.

I shall be careful in alluding to the different facts confided to me, not to mention either names or places, and those who may think fit to send them may rely on my discretion.

I shall be obliged by your giving insertion to this letter, and have the honour to be, sir,

Your obedient servant,

G. J. GUTHRIE.

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE XXIV.

*Protracted and difficult labours, from the
forehead of the child being inclined to
the symphysis pubis; presentation of the
face and superior extremity with the head.*

THE head may present, but the vertex may be in the hollow of the *sacrum*, and the forehead turned or inclined towards the pubes. If the head and pelvis are of the usual dimensions, and the uterine contractions strong, the forehead and face are in most cases gradually forced downward under the symphysis pubis, through the os externum, and the delivery is safely accomplished without any artificial assistance, or the nature of the presentation even being ascertained, till the occiput is found directed to the coccyx, and the face to the pubes, after the expulsion of the head. But if the head be large, the pelvis narrow, and the labour is in consequence protracted, the kind of presentation is discovered on making a more careful examination, by feeling the anterior fontanelle towards the symphysis pubis; or even the root of the nose and eyes may be touched, if the finger is passed sufficiently high up behind the symphysis. In these cases the presenting part is unusually flat towards the arch of the pubes, the parietal bones do not overlap one another in the ordinary manner, the swelling of the scalp does not form so speedily, and not only is the cavity of the *sacrum* imperfectly filled up with the occiput, but the sagittal suture may be distinctly traced

backward to the posterior fontanelle, if the head has not remained long in the pelvis and suffered much from pressure. When this is found to be the position of the foetal head, it does not follow, as Dr. Denman observes, that any thing ought to be done; but we are to wait a longer time, because as experience has proved that the head in this position may be, and almost universally is, ultimately expelled by the natural efforts, so long as these are continued no artificial help should be given or attempted. But when the pains cease, or when we are fully convinced that they are unequal to the exigencies of the case, such assistance must be given as the situation of the patient may require and allow. With this position of the head, besides the greater length of time which may be required for moulding and expelling it, there will also be a greater distension of the external parts; because the hind-head cannot be cleared of the perineum before the chin has descended as low as the inferior edge of the symphysis of the ossa pubis; by which an inconvenience is produced equal to what an increased depth of the cavity of the pelvis would occasion, or a deficiency in the arch of the pubes. "This kind of labour," says Dr. Merriman, "is not in general very unmanageable. The head may be longer than ordinary in passing through the pelvis; but if this be well formed, and the pains are strong, it will be at length excluded, and in the majority of cases the child will be born alive." In the treatment of these cases, then, except guarding the perineum with more than common care while the head is passing through the outlet of the pelvis, nothing peculiar is required to be done. If the labour, however, is much protracted, the head of the child, as represented in the twenty-first table of Smellie, which I now show you (exhibiting it), becomes compressed into a longish form, with a tumor on the vertex, and the natural powers may be insufficient for its expulsion. Various methods have been recommended and adopted by

face being incapable of compression, or of being moulded into the form of the pelvis, like the bones of the cranium, and from the head occupying a greater space in the pelvis than natural. But the head nevertheless, in a great proportion of cases in which the face presents, passes through the pelvis without artificial assistance, and no unpleasant consequence is produced except a swollen state of the child's face from the long-continued pressure, but which soon disappears. Portal was the first who observed that cases of face presentation, though somewhat tedious, usually terminate without the assistance of art, and recommended them to be treated like cases of natural labour. Smellie, as I have already stated, had recourse to the operation of turning, and bringing down the feet in face cases; but I am satisfied that the practice is highly objectionable under any circumstances, and I have not seen a single instance in which it would have been proper. Dr. Merriman, however, seems rather to be of opinion that there are cases, although he does not state that he has actually met with them, in which it might be right to turn and bring down the feet. "I am quite convinced," he says, "that, as a general rule, it is wrong to turn in face cases: yet under some very favourable circumstances such an operation may perhaps be admissible. If, for instance, the head of the

child were found lying above the brim of the pelvis, the membranes unruptured, the os uteri well dilated, and the vagina and the perineum in a state of relaxation, the probability of saving the life of the child would be considerable, and might justify the operator in having recourse to such a proceeding." My firm belief is, that the child, even under such favourable circumstances, would have a far better chance to be born alive if the labour were left wholly to nature, and, if the natural powers were inadequate, to extract it with the forceps. Professor Bang relates ten cases of face presentation; in three, the child was turned, and in every case was still-born. In four, after ineffectual attempts to turn, the children were at length expelled by the pains, and were all still-born. In one, the forceps was used about 24 hours after the labour began. The child was dead. Two were left entirely to nature, and the children were born alive. In most of these cases, observes Dr. Merriman, turning seems to have been undertaken sooner than would allow the parts to be properly dilated. "In thirty-three cases," says Dr. Collins, "the face of the child presented; 4 of the 33 were still-born: with the first, the labour lasted 8 hours, and with the fourth 7 hours; all were delivered without assistance. In 12 cases the head presented with the face to the pubes; 6 of

the 12 children were still-born ; with the first, the mother had been a considerable time in labour before admission ; with the second, there were three convolutions of the funis on the neck ; the labour lasted 16 hours, and the forehead suffered much from compression ; with the third, the mother was deformed, and the pelvis very defective ; with the fourth, the mother had been long in labour before admission ; this was her second pregnancy, and both deliveries were effected with the crotchet : the fifth was a woman with a deformed pelvis : with the sixth, the funis and hand descended with the head. The third, fourth, and fifth, were delivered with the crotchet. By reference to these cases Dr. Collins states that it will be clearly seen that the position of the child did not, in any instance, render artificial delivery necessary.

Smellie's twenty-third table shows, in a lateral view, the face of the child presenting, and forced down into the lower part of the pelvis ; the chin being below the pubes, and the vertex in the concavity of the os sacrum ; the waters likewise being all discharged : the uterus appears closely joined to the body of the child, round the neck of which is one circumvolution of the funis.

"When the pelvis is large," he observes, "the head, if small, will come along in this position, and the child be saved ; for as the head advances lower, the face and forehead will stretch the parts between the frenum labiorum and coccyx in form of a large tumor. As the os externum likewise is dilated, the face will be forced through it ; the under part of the chin will rise upwards over the anterior part of the pubes, and the forehead, vertex, and occiput, turn from the parts below. If the head, however, is large, it will be detained either when higher, or in this position. In this case, if the position cannot be altered to the natural, the child ought to be turned, and delivered footling." "If the pelvis, however, is narrow, and the waters are not all gone, the vertex should, if possible, be brought to present : but if the uterus is so closely contracted that this cannot be effected, on account of the strong pressure of the same, and slipperiness of the child's head, in this case the method directed in the following table is to be taken." (See top of next column.)

This figure represents, in the lateral view, the head of the fœtus in the same position as in the former figure ; but the delivery is supposed to be retarded from the largeness of the head, or a narrow pelvis.

"In this case," says Smellie, "if the head cannot be raised, and pushed up into the uterus, it ought to be delivered with the forceps in order to save the child. This position of the chin to the pubes is one of the safest cases, where the face presents, and

is most easily delivered with the forceps, the manner of introducing which over the ears is shewn in this table. The patient must lie on the back, with her breech a little over the bed, her legs and thighs being supported by an assistant sitting on each side. After the parts have been slowly dilated with the hand of the operator, and the forceps introduced and properly fixed along the ears of the child, the head is to be brought down by degrees, that the parts below the os externum may be gradually stretched ; the chin then is to be raised over the pubes, whilst the forehead, fontanelle, and occiput, are brought out slowly from the perineum and fundament, to prevent the same from being hurt or lacerated. But if the fœtus cannot be extracted with the forceps, the delivery must be left to the labour pains as long as the patient is in no danger ; but if the danger is apparent the head must be delivered with the crotchet. When the face presents, and the chin is to the side of the pelvis, the patient must lie on her side ; and after the forceps are forced along the ears, the chin is to be brought down to the lower part of the os ischium, and then turned out below the pubes, and delivered in a slow manner as above. In these awkward presentations the delivery should be always trusted to the natural pains as long as the patient is in no danger." (See next page.)

This figure shows, in a lateral view of the right side, the face of the fœtus presenting as in the last two figures, but in the contrary position, that is, with the chin to the os sacrum and the head—
"above the pubes, the waters evacuated, &c."
The same truths

different practitioners under these circumstances. Smellie was accustomed, in these and in all cases of face presentation, even when the liquor amnii was evacuated, the first stage of labour completed, and the head of the child was low in the pelvis, to attempt to force back the presenting part and bring down the feet. If you read the histories of some of the cases recorded in his third volume, you will find that, about the year 1746, this was his general practice, but that it was almost always unsuccessful. The operation of turning is never now employed in this country by experienced practitioners, where the membranes have been ruptured, and the head has passed through the os uteri into the cavity of the pelvis. Turning, where the head has advanced so far in the pelvis, is truly a most dangerous operation both for the mother and child, and should never be attempted. If the child cannot be delivered with the labour pains, or turned and brought footling, the forceps, says Smellie, are to be applied on the head as described in this figure, and brought along as it presents; but if that cannot be done without running the risk of tearing the perineum, and even the vagina and rectum of the woman, the forehead must be turned backwards to the sacrum. To do this more effectually the operator must grasp firmly with both hands the handles of the forceps, and at the same time pushing upwards, raise the head as high as possible in order to turn the forehead to one side, by which it is brought into the natural position. This done, the head may be brought and delivered as in natural labour. In several cases of this kind he was obliged to employ the crotchet after trying the forceps. With the short straight forceps, the head may be turned slightly round with safety and advantage, as you depress the handles and bring the forehead and face out under the symphysis pubis; but I believe it to be impossible to perform the operation here described by Smellie, with the long curved forceps represented in the figure, without destroying the child or lacerating the vagina.

"In this case," Dr. F. Ramsbotham correctly observes, "we have the choice of two methods by which to extract the head: we may either bring the face under the pubes, making a quarter turn of the half pelvis, or we may make a three-quarter turn, and throw it into the hollow of the sacrum. Of these modes I should certainly prefer that in which there is the least turn to be made, namely, with the face under the pubes, provided it could be effected; because we are less likely to do injury to the mother and also the child. If we make a three-quarter turn we may injure the mother's parts by bruising and perhaps by laceration; and we might even destroy the child; for if its body be strongly

embraced by the contracted uterus, and do not follow the extensive turn which we cause the head to make, we must infallibly twist its neck to a great extent, and we might dislocate the vertebræ to the destruction of its life."

A safer mode was sometimes employed by Smellie to turn the forehead round to the sacrum. In describing a case of this sort, he states that he "gently opened the os externum during every pain, raising the head a little when the pain began to abate, and moving the forehead to the left side of the sacrum, by which means he effected the delivery." Dr. Merriman says this appears to have been his common practice in such presentations, and that a somewhat similar manœuvre was recommended by Exton. "It is not a little extraordinary," he further observes, "that the late Dr. John Clarke was unacquainted with this direction of Smellie. In his paper on the management of cases in which the face of the child presents towards the os pubis, Dr. Clarke evidently thought that he proposed a novel practice, when he recommended to push the forehead round towards the sacrum. He says, 'all the best writers upon the practice of midwifery have taken notice of this cause of difficulty in labours; but they have been contented with describing it, without suggesting any means more especially suited to this case.' Dr. Clarke directs either one or two fingers to be passed up, between the left side of the head, near the coronal suture or the temple and the symphysis pubis, and steady pressure to be made during a pain against the frontal or parietal bone. Sometimes this method is attended with success, but it most frequently fails, and the head returns to its original position before the pressure was begun to be made. I cannot agree with Dr. Burns in thinking that it would be justifiable, where the presentation was discovered early, to rupture the membranes and turn the vertex round. From all that I have seen of these cases, I am disposed to believe that it is best to leave them to the natural efforts, and to avoid all interference,—all attempts to change the position, while the pains continue regular, and the head advances, however slowly. Dr. Merriman has very recently informed me that he entirely coincides in this opinion. If exhaustion should take place it will then become necessary to deliver artificially, in the manner which will afterwards be described.

This figure from Smellie's Engravings represents the vertex in the concavity of the sacrum, and the forehead turned to the pubes. When the head is small, he says, and the pelvis large, the parietal bones and the forehead, will in this case, as they are forced downwards by the labour pains, gradually

dilate the os externum, and stretch the parts between that and the coccyx in form of a large tumor, till the part come down below the pubes, when the head will be safely delivered. But if the same be large and the pelvis narrow, the difficulty will be greater, and the child in danger, as in the following figure, also copied and slightly altered from

Smellie; the short straight forceps being represented instead of the long curved forceps you have seen in the original engraving. By looking at this figure you will be able to form a good idea of the extent to which the neck of the child would be twisted by turning the face entirely round into the hollow of the sacrum.

Protracted and difficult labours from presentation of the face.

The face is readily distinguished from every other part of the foetus by the inequality of its surface, and by the eyes, nostrils, mouth, and chin. The mouth, as represented in the following figures from Smellie's Plates, may either be under the symphysis pubis, with the vertex occupying the hollow of the sacrum, or it may be situated close to the lower end of the sacrum and coccyx, with the vertex behind the symphysis pubis. The first of these positions is considered the most frequent and favourable; but the head, in a great proportion of cases, whether it be situated in this or in the second position, is expelled by the natural efforts, though a longer period than usual be required for the completion of the labour. The difficulty arises from the bones of the

the child were found lying above the brim of the pelvis, the membranes unruptured, the os uteri well dilated, and the vagina and the perineum in a state of relaxation, the probability of saving the life of the child would be considerable, and might justify the operator in having recourse to such a proceeding." My firm belief is, that the child, even under such unfavorable circumstances, would have a far better chance to be born alive if the os uteri were left wholly to nature, and, if the natural powers were inadequate, to extract it with the forceps. Professor Bang relates ten cases of face presentation: in three, the child was turned, and in every case was still-born. In four, after ineffectual attempts to turn, the children were at length extracted by the pains, and were all still-born. In one the forceps was used about six hours after the labour began. The child was dead. Two were left entirely to nature, and the children were born alive. In all of these cases observes Dr. Merriman, "nothing seems to have been undertaken except what would allow the parts to be presented as they were." In thirty-three cases," says Dr. Merriman, "the face of the child presented, and of the 33 were still-born: with the first the mother lasted 5 hours, and with the last 12 hours: all were delivered with assistance. In 12 cases the head was above the pubes: 6 of

child were found lying above the brim of the pelvis, the membranes unruptured, the os uteri well dilated, and the vagina and the perineum in a state of relaxation, the probability of saving the life of the child would be considerable, and might justify the operator in having recourse to such a proceeding." My firm belief is, that the child, even under such unfavorable circumstances, would have a far better chance to be born alive if the os uteri were left wholly to nature, and, if the natural powers were inadequate, to extract it with the forceps. Professor Bang relates ten cases of face presentation: in three, the child was turned, and in every case was still-born. In four, after ineffectual attempts to turn, the children were at length extracted by the pains, and were all still-born. In one the forceps was used about six hours after the labour began. The child was dead. Two were left entirely to nature, and the children were born alive. In all of these cases observes Dr. Merriman, "nothing seems to have been undertaken except what would allow the parts to be presented as they were." In thirty-three cases," says Dr. Merriman, "the face of the child presented, and of the 33 were still-born: with the first the mother lasted 5 hours, and with the last 12 hours: all were delivered with assistance. In 12 cases the head was above the pubes: 6 of

the 12 children were still-born ; with the first, the mother had been a considerable time in labour before admission ; with the second, there were three convolutions of the funis on the neck ; the labour lasted 16 hours, and the forehead suffered much from compression ; with the third, the mother was deformed, and the pelvis very defective ; with the fourth, the mother had been long in labour before admission ; this was her second pregnancy, and both deliveries were effected with the crotchet : the fifth was a woman with a deformed pelvis : with the sixth, the funis and hand descended with the head. The third, fourth, and fifth, were delivered with the crotchet. By reference to these cases Dr. Collins states that it will be clearly seen that the position of the child did not, in any instance, render artificial delivery necessary.

Smellie's twenty-third table shows, in a lateral view, the face of the child presenting, and forced down into the lower part of the pelvis ; the chin being below the pubes, and the vertex in the concavity of the os sacrum ; the waters likewise being all discharged : the uterus appears closely joined to the body of the child, round the neck of which is one circumvolution of the funis.

"When the pelvis is large," he observes, "the head, if small, will come along in this position, and the child be saved ; for as the head advances lower, the face and forehead will stretch the parts between the frænum labiorum and coccyx in form of a large tumor. As the os externum likewise is dilated, the face will be forced through it ; the under part of the chin will rise upwards over the anterior part of the pubes, and the forehead, vertex, and occiput, turn from the parts below. If the head, however, is large, it will be detained either when higher, or in this position. In this case, if the position cannot be altered to the natural, the child ought to be turned, and delivered footling." "If the pelvis, however, is narrow, and the waters are not all gone, the vertex should, if possible, be brought to present : but if the uterus is so closely contracted that this cannot be effected, on account of the strong pressure of the same, and slipperiness of the child's head, in this case the method directed in the following table is to be taken." (See top of next column.)

This figure represents, in the lateral view, the head of the fœtus in the same position as in the former figure ; but the delivery is supposed to be retarded from the largeness of the head, or a narrow pelvis.

"In this case," says Smellie, "if the head cannot be raised, and pushed up into the uterus, it ought to be delivered with the forceps in order to save the child. This position of the chin to the pubes is one of the safest cases, where the face presents, and

is most easily delivered with the forceps, the manner of introducing which over the ears is shewn in this table. The patient must lie on the back, with her breech a little over the bed, her legs and thighs being supported by an assistant sitting on each side. After the parts have been slowly dilated with the hand of the operator, and the forceps introduced and properly fixed along the ears of the child, the head is to be brought down by degrees, that the parts below the os externum may be gradually stretched ; the chin then is to be raised over the pubes, whilst the forehead, fontanelle, and occiput, are brought out slowly from the perineum and fundament, to prevent the same from being hurt or lacerated. But if the fœtus cannot be extracted with the forceps, the delivery must be left to the labour pains as long as the patient is in no danger ; but if the danger is apparent the head must be delivered with the crotchet. When the face presents, and the chin is to the side of the pelvis, the patient must lie on her side ; and after the forceps are forced along the ears, the chin is to be brought down to the lower part of the os ischium, and then turned out below the pubes, and delivered in a slow manner as above. In these awkward presentations the delivery should be always trusted to the natural pains as long as the patient is in no danger." (See next page.)

This figure shows, in a lateral view of the right side, the face of the fœtus presenting as in the last two figures, but in the contrary position, that is, with the chin to the os sacrum and the bregma to the pubes, the waters evacuated, and the uterus contracted. The same treatment is recommended.

Labour is sometimes protracted and difficult, from one of the extremities descending along with the head. The hand of the child may be felt closely applied, in some cases, to the side of the head, before it has entered the brim of the pelvis; and if the pelvis is large, and the uterine action strong, they may be expelled together without assistance. But, under the most favourable circumstances, the hand adds much to the size of the head; and if the pelvis be small or distorted, they become impacted in the brim or outlet. The difficulty is still greater if the arm descends along with the head or before it, and the natural efforts may be insufficient, in this case, for the completion of the labour. Whether it be the hand or arm which presents along with the head, it is advisable in all cases to push it up beyond the head, and to hold it up until the head has come down so low as to occupy the brim of the pelvis completely, and it is impossible for the hand or arm again to descend by the side of the head or before it, and impede its progress through the pelvis. You will not succeed in pushing the hand or arm above the head of the child unless you introduce the whole of your hand into the vagina, and partially through the os uteri, and with your fingers press up and hold up the hand or arm of the child between the pains, until the

head has sunk down so far as to be clear of the obstruction. In some cases, by doing this, a labour which has been protracted for many hours is brought, after a few pains, to a successful termination. Without introducing your whole hand into the vagina, you will most frequently fail in obviating the difficulty, and you may be compelled to have recourse to the forceps, or to the perforator, if the head and arm should become jammed in the brim. In a case which I lately saw, in consultation with Mr. Taylor, of Leicester Square, the head, left arm, and funis of the child, without pulsation, presented; the membranes were ruptured, and the uterus closely contracted around the child. As the child was dead, I opened the head and drew it readily down before the arm and delivered. Had the cord been pulsating, the operation of turning, I suppose, would have been the proper practice, though, under the unfavourable circumstances, there would have been little or no chance of preserving the child's life, and the uterus might have been injured in the delivery.

A foot may present along with the head, and obstruct its progress through the brim of the pelvis. On the 1st of June, 1842, at mid-day, I saw a case in Buckingham Place, Fitzroy Square, in which the head, the funis, and a foot presented. Labour began the

previous afternoon : at 6 o'clock the liquor amnii escaped, and the midwife felt the head, a foot, and a great loop of the funis presenting. She thought the proper practice was to put back the foot, and this she attempted to do for six hours. At midnight she requested a surgeon to see the case, and deliver the woman, but he did nothing except administer two doses of the ergot of rye. In this condition the patient remained till 12 o'clock the next day, when I saw her. As there was no pulsation in the cord, the only subject for consideration was, how the patient might be relieved with the least risk. I passed up my hand into the vagina, grasped the foot, and brought down the nates, while, at the same time, I pushed the head aside and easily delivered. If the head had not gone up by the pressure, I would have opened it, and delivered with the crotchet, without paying any attention whatever to the foot. In a protracted labour which came under the care of Dr. John Ramsbotham in 1820, he found the head above the brim of the pelvis with the foot down by its side. Without withdrawing the hand, which had been passed into the vagina, he pushed up the foot, and at that moment a strong uterine contraction coming on, the head was brought down into the brim, so that the foot was left above. Keeping the hand in that situation till another pain came on, he found the head descend without the foot. In pushing up the foot a hand also was felt just by the side of the head. The case was then left to the natural action of the uterus, and in about two hours a living child was expelled.

CASE OF DIABETES MELLITUS,

WITH NUMEROUS OBSERVATIONS,
AND A REVIEW OF THE PATHOLOGY AND
TREATMENT OF THIS DISEASE.

By JOHN PERCY, M.D. (Edin.)

Physician to the Queen's Hospital, and Lecturer
on Organic Chemistry at the Royal School of
Medicine and Surgery, Birmingham.

[Continued from page 93.]

To the inquirer of chemical pathology, there is no disease more deeply interesting than diabetes mellitus. The formation of grape-sugar in the system in large quantity, and its elimination by the kidneys, are facts well calculated to arrest the attention of the reflective mind; and, accordingly, we find that the disease in question has frequently been made the subject of minute investigation, as well as fanciful speculation; and yet its pathology

continues to be involved in considerable obscurity. To our countryman, Dr. Prout, not less distinguished as a philosophic and practical chemist than as a philosophic and practical physician, we are indebted for much valuable knowledge concerning diabetes. And I may avail myself of this opportunity of expressing my satisfaction that the labours of that correct and discriminating mind in respect to the very foundation of chemical science have at length begun to receive remarkable confirmation from other chemists; and, by way of illustration, I may mention the beautiful results recently obtained by Messrs. Dumas and Stas in the determination of the atomic weight of carbon. It is not my intention, in the following pages, to present an elaborate detail of the various opinions which have been entertained from remote antiquity to the present day respecting the nature and cause of diabetes; for laborious details of this kind may be found in numerous monographs and treatises, and of these I may mention especially the treatise of Dr. Latham (London, 1811, pp. 244). I propose, so far as my humble ability will permit, carefully to review the well-ascertained *facts* of diabetes, and those of physiology relating to the subject, with a view to arrive at such conclusions as appear to be warranted by the present state of our knowledge. I have performed numerous physiological experiments, which have been suggested either by reflection or by the statements of physiologists, and I have obtained results diametrically opposed to some of these statements. I am deeply sensible of the responsibility imposed upon the man who appeals to nature in the way of experiment; for any erroneous conclusion, whether the effect of inadvertence or inaccuracy in experimenting, is worse than ignorance, inasmuch as it is positive error. I hope that I have attempted in this, and shall ever continue, in similar investigations, to dispossess my mind of every thing but an honest desire to discover truth. I shall relate minutely each experiment, that the reader may be enabled to judge how far my results are worthy of his confidence; and this must be my ground of apology for what might appear to be tedious and superfluous detail. There is one point on

which I am especially anxious to offer a few observations, and that is, the extreme difficulty, not to say impossibility, of acquiring comprehensive information in any scientific department in a provincial town. A man, before he sits down to write on any particular subject, should be acquainted with all that has been previously written upon this subject; but if this condition were absolutely indispensable and imperative, few men in the provinces would be found qualified to write. There are numerous papers relating to diabetes in various periodical works, French and German, which I have been extremely desirous of consulting, and which desire it has been impossible for me to gratify; for Birmingham cannot at present boast of an extensive medical library. If, then, I should be found to betray ignorance in some respects of the labours of continental writers, it will, I hope, be charged, not to wilful negligence on my part, but to the impossibility of my obtaining access to their writings where I now reside.

OBSERVATIONS AND EXPERIMENTS CONCERNING DIABETES MELLITUS.

Ist. Of the formation of grape-sugar, and its elimination by the kidneys.—The question which is first suggested by this part of the subject is, whether grape-sugar is produced in the healthy system? Let us first examine recorded observations. “*Sugar* is not found in the blood in a state of health, but has been many times distinctly recognised in the blood of diabetic individuals, where it probably always exists in a greater or less degree. Sugar, also, is not a natural ingredient of the urine, but is found in large quantities in that fluid in the disease just mentioned (diabetes). I am not aware that sugar has been ever found in the blood, or even in the urine, of any inferior animal, which may be considered a remarkable circumstance.” (*Stomach and Urinary Diseases*, Dr. Prout, 3d edit. Introduction, p. xciii.) “Now the reduction of all the forms of the saccharine principle appear to be accompanied by the development of a *low sugar*; which low sugar, in the healthy condition of the stomach, is speedily converted into albuminous and oleaginous matters. Hence, as the existence of sugar in the stomach is only momentary, or, as it were, a point

in transitu, its presence in the healthy organ is with difficulty detected . . . The first step in the derangements, therefore, producing the disease called diabetes, does not consist, as some have supposed, in the development of the sugar in the stomach, which is a natural process.” (Dr. Prout, *op. cit.* p. 16). From these statements, then, we conclude that Dr. Prout admits the formation of a sugar in the stomach as a process of healthy digestion. Tiedemann and Gmelin found that “boiled starch (in the stomach of a dog) was, in the course of a few hours, converted into gum of starch and sugar.” (*Müller's Elements of Physiology*, translated by Baly, vol. i., p. 578.) Saliva has the property of converting starch into sugar. *Müller, op. cit.* p. 577; *Dr. Wright on the Saliva, Lancet*, 1842) “Thus, amylaceous matters (in digestion) are converted into gum and sugar; the saccharine matters are absorbed.” (*Dumas, Essai de Statique Chimique des Etres Organisés*, 1842, p. 41). Probably, numerous other authorities might be cited in answer to the question proposed, but the preceding suffice to show that the conversion of starch into sugar in the stomach is generally admitted to occur in the condition of health. Now, before proceeding to the detail of direct experiments on this point, so deeply interesting and important, let us inquire concerning the introduction of *saccharine* matters into the stomach, with a view to ascertain whether such matters can be *directly* absorbed. Magendie fed dogs exclusively upon sugar and water, and the urine of these animals was examined by the accurate and laborious Chevreul. It was “found to be alkaline, as in herbivorous animals, and to contain no uric acid or phosphates.” (*Müller, op. cit.* vol. i., p. 526). No mention is made of the existence of sugar in such urine. “We know that the urine of dogs, fed for three weeks exclusively on pure sugar, contains as much of the most highly nitrogenized constituent, urea, as in the normal condition.” (*Marchand, Erdmann's Journal für praktische Chemie*, xiv. p. 495; *Animal Chemistry, &c.* Liebig, pp. 61-62.) No mention is made of sugar. Neither does the martyr, Dr. Stark, appear to have observed any saccharine condition of his urine

when subsisting principally on a diet of saccharine matter, although his urine was occasionally, during this period, much increased in quantity. (*The Works of the late William Stark, M.D. &c. Lond. 1788, 4to. pp. 131, 163, &c.*) On the other hand, on the authority of Dr. Krimer, "When diabetic urine is introduced into the stomach of an animal, we find, on the following day, saccharine matter in its urine, and continue to do so so long as we administer this substance, and even some days after we have ceased to inject it." (*Bell's Essay on Diabetes. translated by Markwick, p. 48.*) I have made several experiments on this subject. I proceeded first to ascertain whether direct absorption of saccharine matter in the stomach would occur when the most favourable conditions of absorption were presented, namely, *fasting* and the *abstraction of blood*.

Experiment I.—March 14th. I selected a small mongrel dog, which had not been fed since the 11th, although it is probable that during this interval he picked up scraps of food. He was fat, and in good condition. He ate the sugar of raisins, crystallized, and in the state of thick paste; he drank water afterwards. In the course of half an hour I injected into the stomach about the same quantity as he had eaten, dissolved in water. I suppose that altogether he must have had about three ounces, although I did not ascertain the precise amount, of dry sugar. In another half hour, I opened the right jugular vein, and collected the blood. No urine was evacuated. I then destroyed the animal with strong hydrocyanic acid, which occasioned vomiting and slight general convulsive action. No urine, however, contrary to what is the usual effect of the poison, was voided. As soon as the heart ceased to beat, I removed the bladder, which was distended by limpid urine. The stomach contained solution of sugar, as manifested by the odour and appearance, and a few pieces of straw were also observed. I added a small quantity of yeast to the urine, which was introduced into a graduated receiver over mercury; it occupied the volume of 1.2 cubic inch. Late in the evening, about two hours after the experiment was arranged, I observed that gas was sensibly evolved. On the following morning the tube was completely

filled with gas, all the liquid having been forced out; and the gas was under considerable pressure, as the tube, of which the capacity was $2\frac{1}{4}$ cubic inches, was retained midway in mercury. All the gas was immediately absorbed by solution of caustic potash. I had not expected this striking result; otherwise I should have employed a graduated receiver of much larger capacity. The blood was examined with a view to the detection of sugar, but, owing to an accident, the result is not satisfactory.

Experiment 2.—March 24th. Since the 18th, a middle-sized mongrel dog was fed exclusively on common brown (cane) sugar and water. Altogether, he had taken 4 lbs. avoirdupois. He drank freely of cold water. He was observed occasionally to have fits, during which he turned round and foamed at the mouth: fits of this kind not unfrequently occur during the distemper. These fits were not noticed previously to his feeding on sugar, although it is possible he might have had them. He appeared tolerably lively, and was daily led about for exercise. On the 23d, he was carefully watched for ten hours in succession, in order to collect any urine which might be voided, but without success, as no urine was passed during this period. He was much purged, and the fæces were liquid and dark. This morning (24th), at half-past 10, he ate about $\frac{1}{4}$ lb. of sugar, and afterwards drank water. He was again watched until 2 P.M. when, having passed no urine since half-past 10, he was destroyed by hydrocyanic acid. During the convulsive action which followed, he evacuated only a small quantity of urine, which I collected; some brown liquid escaped through the nostrils. I immediately opened the body, and collected what urine remained in the bladder by pressing this viscus. Here I may relate the post-mortem appearances, as illustrating, in a certain degree, the influence of an exclusively saccharine diet.

Chest: the *lungs* did not much contract. They were gorged with frothy colourless liquid; I think I never saw before so large a quantity of liquid escape from the trachea and bronchi. The *liver* was large, and apparently healthy. *Abdomen:* the *spleen* contained minute light-coloured specks, such as I have before occasionally seen

in the spleen of dogs. The *kidneys* were natural. In the *stomach* was a small quantity of brown liquid, mixed with dark flocculent matter, and having the smell of brown sugar; I found, also, some small pieces of straw. Except in the vicinity of the pylorus, the mucous membrane presented the usual light plum-tint. The summits of the rugæ throughout had a red blush; the intervals were pale. The *intestines* contained liquid brown *fæculent* matter; which, in the rectum, was pasty, and similar to that evacuated during the action of the hydrocyanic acid. The odour of the *fæces* was not particularly *fœtid*. The contents of the stomach and intestines had a decided acid reaction.

Urine: taste *salt*, and not in the slightest degree *sweet*. I collected *f3ss.* precisely. Pale straw. Strongly acid, immediately reddening litmus; sp. gr. more than 1040°. I mixed *f3ij.* with a minute quantity of fresh yeast in a graduated jar over mercury; distilled water was added. The volume occupied by the liquid was 1·4 cubic inch: 2·6 cubic inches of gas were evolved, and instantly absorbed by caustic ley. I then distilled the fermented liquid with carbonate of potass in the chloride of calcium bath. I obtained only a minute quantity of incombustible liquid, which had a decided ammoniacal odour, and immediately restored the colour of reddened litmus. To the product I added carbonate of potass, when a supernatant stratum, a quarter of an inch in depth, was formed. By means of an extremely fine pipette, I removed some of this stratum, and found it to burn readily with a blue flame. I have preserved this specimen in a hermetically sealed tube.

The remaining *f3ij.* of urine were evaporated over the steam-bath. I obtained a clear brown syrup, to which I added nitric acid in excess, and stirred well. March 25th.—No crystallization of nitrate of urea. 30th.—Still no crystallization. I then evaporated in order to ascertain whether *oxalic acid* would be produced. I procured minute and distinct colourless crystals, which occasioned a precipitate in a solution of chloride of calcium, insoluble in acetic acid. I should be inclined to infer, from the small quantity of gas evolved by fermentation,

and the quantity of *oxalic* generated, that this acid was probably derived in part from the *colouring* or other *organic matter* of the urine besides *true sugar*.

Experiment 3.—March 29th. Since the morning of the 27th, a large bull-terrier dog was fed entirely on common brown (cane) sugar and water. At first, he ate freely $\frac{1}{2}$ lb. Altogether, he took 2 lbs. Yesterday, and early this morning, he evacuated light brown, watery, and offensive *fæces*. At $\frac{1}{2}$ before 8 this morning, he ate $\frac{1}{2}$ lb. of similar sugar, and drank $\frac{1}{2}$ pint of water. At 10 A.M. he freely passed urine: *f3v.* were collected. Colour brown. Odour peculiar. Feebly reddened litmus. Taste *not* sweet even in the slightest degree. Surface covered with minute and peculiar crystals, not resembling in form the ordinary ammoniaco-magnesian phosphate. I examined these crystals minutely, but, in this place, I need not describe them. Filtering paper was stained yellow by this urine. I mixed 1·2 cubic inches of the urine with a minute quantity of fresh yeast over mercury in a graduated receiver. April 1st, 9 $\frac{1}{2}$ P.M. Temp. 59° F. Barometer not observed. I measured 5 cubic inches of gas. The fermented urine was then distilled for a few minutes *per se*, and to the product was added carbonate of potass. I obtained a supernatant stratum of spirit $\frac{1}{8}$ inch in diameter, and $\frac{1}{8}$ in depth. It burnt with a blue flame. The specimen is preserved.

I evaporated over the steam-bath 500·0 grains of urine, and obtained a brown syrup, having a strong smell. On the addition of nitric acid, crystals of nitrate of urea were separated in *small* quantity. No coagulation was produced.

From these experiments, then, we are justified in concluding that *sugar* existed in the urine, after its introduction into the *stomach*. In the first experiment sugar was found in the urine, in a very short time after the animal had received sugar by the mouth. We shall also be justified in concluding that in these cases the sugar passed directly into the blood, and was simply eliminated by the kidneys; provided we ascertain by experiment that the urine of a dog, which has not taken sugar, does not undergo fermentation by the addition of yeast. Accordingly, the following experiment was made.

Experiment 4.—April 3d. The dog which was the subject of Experiment 3 was fed on horseflesh and potatoes since March 29th. The urine was readily collected this morning. Odour strong and peculiar. Reaction acid. Amber-coloured. Sp. gr. 1046°. I mixed 1·1 cubic inches with a small quantity of fresh yeast in a graduated tube over mercury. In the evening, no gas had been evolved. April 4th, *morning*. Not the slightest disengagement of gas; *evening*, 7½, still not the slightest evolution of gas. It must be remarked that, as nearly as possible, the same condition of temperature was preserved in all these experiments. One cubic inch of carbonic acid gas evolved corresponds nearly to one grain of grape sugar. In Experiment 2, then, we should have about 10 grains in the fluid-ounce, and 160 in the pint.

Now, in these experiments, it must be admitted that the conditions under which the absorption of sugar was effected were in a greater or less degree artificial, for sugar was present in the stomach in *inordinate* quantity, and the animals were exposed to peculiar circumstances. It is, however, probable, that, in the healthy state, when sugar is introduced into the stomach in small quantity, even supposing it to pass directly into the circulation by absorption, it is never eliminated by the kidneys, but supplies material either for assimilation of some kind or other, or for pulmonary oxidation. The following experiments concerning the injection of sugar into the veins relate directly to this part of the subject.

Experiment 5th.—March 22d. Into the right jugular vein of a large mongrel-mastiff dog, which had not been fed since the previous morning, I injected 200 grains of the crystallised residuum of Merchant's urine dissolved in fʒij. of warm distilled water. No symptoms, except such as might be referred to the operation and consequent excitement, followed. In 1½ hour afterwards I poisoned the animal with anhydrous hydrocyanic acid, and collected 4½ fluid-ounces of deep amber-coloured urine, voided during the convulsive action. A small quantity escaped, and some also remained in the bladder, and was obtained by squeezing that viscus *in situ*. Odour peculiar. Sp. gr. 1040°. Reddens litmus. I mixed the whole quantity with a small

proportion of yeast, in a two-necked bottle, precisely as in the examination of Merchant's urine.

March 24th.—Potash bulb apparatus
after 585·22

March 22d.—Potash bulb apparatus
before 585·15
-07

Here, the increase is so small, that it may be entirely neglected; and we may conclude that no sugar had passed into the urine.

Experiment 6.—March 29th. Into the right jugular vein of a powerful bull-terrier dog, I injected 500 grains of the residuum of Merchant's urine, dissolved in fʒij. of warm water. Half an hour afterwards I destroyed him with hydrocyanic acid. No urine, however, was evacuated. The body was immediately opened, when the bladder, which was distended with urine, was removed. The stomach contained food. The heart was large. There was but little fat, and the muscular fibre was every where firm. The animal was in excellent condition.

Urine.—I collected 4 fluid-ounces and 1 dram. Colour brown. Taste not sweet, but saltish. Odour peculiar. Nitric acid added to this urine *cold* occasioned considerable effervescence, but no coagulation. Hydrochloric acid also produced effervescence. Sp. gr. 1041°. fʒij. were mixed with a small quantity of yeast, and left to ferment in the usual manner.

April 1st, 9½, P.M.—Potash apparatus
after 594·19

March 29th, 9½, P.M.—Potash apparatus
before 585·21
8·98

The ley had risen in the large bulb, and the carbonic acid was displaced in the usual manner by atmospheric air. I evaporated some of the urine over the steam-bath; it evolved a peculiar and very disagreeable odour, not very unlike phosphuretted hydrogen. Considerable effervescence occurred on the addition of strong nitric acid to the syrup *cold*, and an abundance of almost colourless crystals of nitrate of urea was immediately separated.

Experiment 7.—March 2d, ¼ before 5, P.M. Into the right jugular vein of a middle-sized mongrel bitch, I injected a considerable quantity, probably an ounce and a half moist, of the sugar of raisins, dissolved in warm water. Urine

was evacuated. The breathing became somewhat laboured, and the dog appeared drowsy. He was closely watched for 3½ hours, with the intention of collecting his urine. During this period he vomited chyme, and, afterwards, tenacious mucus-like liquid. I then poisoned the animal with strong hydrocyanic acid. During the convulsive action I collected f3vj. of clear brown urine, having an odour *sui generis*, and resembling that of the dog's hide. More urine was passed than I obtained.

Urine.—Transparent. Colour brown. Reddens litmus. Sp. gr. 1031°. Taste not in the least degree sweet. 500 grains were mixed with a small quantity of yeast.

March 4th.—Potash apparatus after fermentation 588.08

March 2d.—Potash apparatus before fermentation 585.81
2.27

250 grains of this urine evaporated over steam-bath left 18.6 of dark brown extract.

Experiment 8.—In this experiment I was aided by my respected friend Dr. Wright. Into the right jugular vein of a middle-sized terrier, we injected at 11, A.M. in successive syringefuls, nearly 1500 grains of white (cane) sugar, dissolved in f3iv. of warm distilled water. The act of injecting occupied 20 minutes. The heart's action at first became irregular and intermitting; then, strong, rapid, and regular; 180 in the minute, as nearly as I could count. This excitement, however, was only temporary, for the pulsations became irregular and intermitting, 92 in a minute. The respiration was somewhat laboured, and the dog appeared drowsy. At 20 minutes before 12, reddish, sweet, and turbid urine was passed, and continued to be voided almost continually, sometimes stillatim, and at other times copiously, until death at 12; life was nearly destroyed by bleeding from the jugular vein, and then completely extinguished by anhydrous hydrocyanic acid, of which the effect was neither so powerful nor so rapid as upon an animal in ordinary circumstances. During the bleeding, towards the last, general convulsive action occurred, with the evacuation of a small quantity of offensive *fæces*. We examined the body ¼ before 3, P.M.: lungs collapsed considerably.

Nothing abnormal in the thorax: no effusion. The intestines were pale and blanched. Half a fluid-ounce of clear serous liquid was collected in the peritoneal cavity; and on cooling, for the body was yet warm, it became thick, concreted into an albuminous mass like the white of egg, and presented a membraniform appearance. The kidneys appeared natural. The bladder was completely contracted, and contained a small quantity of coagulated blood. The mucous membrane of the viscus presented several bloody points. The sp. gr. of the urine first collected was 1046.7; sp. gr. of that collected towards the last was 1050. It contained blood, as the red particles subsided after a short time. 500 grains of the first urine left by evaporation 62.3 of crystallised sweet mass. I obtained beautifully perfect crystals of cane sugar, and have preserved them.

From the experiments which have now been related we learn the following facts:—

1. When grape-sugar is present in the blood in a certain quantity, a portion of it is speedily eliminated by the kidneys, and may be found in the urine.

2. When grape-sugar is present in the blood only in small quantity (*Experiment 5*), it does not pass into the urine in an appreciable degree. In this case it probably undergoes oxidation in the lungs.

3. When cane-sugar is present in the blood in a certain quantity, a portion of it passes into the urine as cane-sugar. It does not appear to be converted in the smallest proportion into grape-sugar, during its passage through the blood. (*Experiment 8*).

4. When cane-sugar is present in the blood, in large quantity, (*Experiment 8*), it exerts a powerfully diuretic action, and the urine evacuated appears to be principally solution of sugar.

5. When grape-sugar is introduced into the stomach (*Experiment 1*), under conditions favourable to absorption, a portion of it is rapidly absorbed (possibly by the veins?) and passes into the urine.

6. When a dog is fed upon cane-sugar and water, a portion of the sugar may be found in the urine.

Before proceeding, it is proper to mention, that my results do not exactly

accord with those previously published. It is stated, in the "Essay on Diabetes" (by Bell, translated by Markwick, p. 49), that "by injecting into the vessels a solution of cane-sugar, we do not find that the sugar passes into the blood or urine, but by the pulmonary transpiration. We know that cane-sugar, taken into the stomach in whatever quantity, never passes by the urine." The authority upon which these statements are made is not mentioned. There is, evidently, an error in the construction of the first sentence, which has, doubtless, escaped the attention of the translator, for it is impossible that sugar can be injected into the vessels (if blood-vessels be meant), and not pass into the blood. Again; Dr. Krimer, as I have already remarked, states, that "when diabetic urine is introduced into the stomach of an animal, we find on the following day saccharine matter in its urine, and continue do so as long as we administer this substance, and even some days after we cease to inject it." (Op. cit. p. 48.) When grape-sugar is introduced into the stomach of a dog, I have been unable to discover a trace of sugar in its urine on the following morning. The dog which was the subject of Experiments 3 and 4, ate 10 ounces of moist sugar of raisins at 9½, A.M. and drank a small quantity of water. On the following morning at 10½, his urine was collected. I obtained precisely f3j. of a pale brown colour. In the evening, it was evaporated, and mixed, while yet warm, with a small quantity of yeast in a graduated receiver over mercury. The volume occupied by the liquid was 0.6 cubic inches. On the following evening, 7, P.M. not the slightest disengagement of gas had occurred.

I have not succeeded in detecting sugar in the urine of man after the introduction of grape-sugar into the stomach. I am not disposed to incur the risk of disordering my own stomach by experiments of this kind, and, therefore, I am unwilling to practise upon the stomachs of others. However, from the preceding experiments upon dogs, we shall, probably, not err in concluding that under similar circumstances similar results would be obtained with man. In my next communication I shall revert to the question at first propounded, concerning the formation of

sugar in the system in a state of health, and shall then detail a variety of experiments performed in reference to this subject.

ESSAYS ON THE DISEASES
OF THE
HEART, GREAT VESSELS, AND
CIRCULATING FLUID.

By R. WILLIS, M.D.

Lecturer on the Principles and Practice of Medicine in the Aldersgate Street School of Medicine, late Physician to the Royal Infirmary for Children, &c.

[Continued from p. 870 of preceding volume.]

SPECIAL PATHOLOGY OF THE HEART.

Malformations of the Heart.

THE heart is subject to a great variety of congenital affections, the majority of which, as they rather interest the morbid anatomist than the practical physician, do not require any particular notice in this place. Sometimes the heart is not in its usual situation; it is contained in the abdomen, or in a pouch outside the thorax; or otherwise, and this is of much less importance, it is merely transposed, the apex of the organ being directed to the right instead of the left side of the chest. Such cases fall under the category of misplacements of the heart—*ectopiæ cordis*. Sometimes, again, the heart consists of but two great cavities instead of four, one representing the auricles, another the ventricles. Occasionally the arteries arise amiss, the aorta springing from the right, the pulmonary artery from the left ventricle, &c. These various states are by no means incompatible with life within the uterus; but they are, for the major part, altogether inconsistent with existence apart from the body of the parent.

Cyanosis.

Among the most important of the congenital malformations of the heart with which we are acquainted, and which do really interest us as practitioners of medicine, are those with which the affection denominated cyanosis, or blue disease, in young subjects, is connected.

Cyanosis is characterized by the skin having more or less of a livid or blue colour, especially in those situations where the capillary vessels of the ge-

neral tegumentary membrane are most conspicuous, or where this membrane is most delicate, as in the lips, the cheeks, and under the nails. The mucous membrane of the mouth and nostrils also presents a livid instead of its usual bright scarlet tint. This livor of the general surface is accompanied by habitual dyspnoea, tumultuous action of the heart, irregularity and intermittence of the pulse at the wrist, and an inferior capacity to engender caloric. The dyspnoea and irregular action of the heart, generally more or less felt at all times, are greatly aggravated upon occasion. Slight efforts, the act of coughing, of going to stool, and the like, are apt to bring on fits of suffocation, and, when the disease is far advanced, attacks of leipothymia, in one of which the patient commonly expires.

Young subjects affected with cyanosis are extremely susceptible to cold. They, in fact, scarcely maintain their temperature at the 98° F., which is held the standard for man in temperate latitudes. It has been found three and four degrees lower under the tongue.

Cyanosis is usually apparent from the period of birth. The new-born infant is familiarly known to have a much darker colour than it acquires immediately after the play of the lungs is fully established, and the circulation through the umbilical cord has ceased. The colour can be observed brightening visibly. This is not the case in the infant that is to be the subject of cyanosis. From the birth it presents a livid or purple hue; and if this be very deep, it will in general scarcely survive more than a few days or weeks. If the livor be less, the child may struggle on languidly for a longer time; and if still less, it may attain to maturity of years. It is not, indeed, very rare for children who have presented a decided blue colour of the tongue and lips and general surface from their birth, to reach the period of puberty, when they very commonly perish. Such children have been observed to grow tall and slender; their muscular system is but very slightly developed; their extremities seem to consist of little more than skin and bone; they are fragile beings, upon whose likelihood of long life no venture can be made. Nevertheless, we cannot always say precisely that cyanosis, even when pretty well

marked in infants, is necessarily to continue and prove fatal in the end. About a year and a half ago I was consulted in regard to a *blue child* about six weeks old. This infant had all the usual indications of cyanosis perfectly well marked; the whole surface was of a pale livid hue; the tongue and lips and finger-nails were purple. It did not seem to suffer any inconvenience, however, and I was assured by the nurse and the parents that the colour was now lighter than it had been. I recommended that the infant should be kept very warm, and particular attention paid to the nursing; and ventured to express a hope that, as matters had mended to a certain extent, they might improve still farther. And this has actually taken place; the infant throve again; the livor of the surface and mouth became less and less conspicuous, and at the present time the child would not be remarked as differing from other children of the same age. Such cases I can imagine to be more frequent than is generally supposed.

The occurrence of cyanosis appears to have been connected at an early period in modern pathological inquiry with an imperfect condition of the partition between the right and left auricles of the heart. Morgagni and Senac, however, were the first who particularly fixed the attention of physiologists upon this state as explaining the phenomena of the disease, which, as may be anticipated, were attributed to an admixture of the venous and arterial blood, and the circulation of an imperfectly aerated fluid. A patent state of the foramen ovale, a normal condition in the foetus, was long universally received as the cause of cyanosis.

There can be little doubt but that cyanosis is frequently connected with such a state of the inter-auricular septum; but the celebrated Corvisart, and then Dr. Crawford, of Dublin, showed that cases of cyanosis occurred which were not referable to any such organic imperfection; and, on the contrary, many cases are now on record in which the freest communication between both auricles, and even between both ventricles, has been discovered, without the fact having been proclaimed during life by a single symptom of cyanosis. In one very remarkable instance, the particulars of which are contained

in the Transactions of the King's and Queen's College of Physicians of Dublin, the communications between the two sides of the heart were so large that the organ might have been considered as single, or as consisting of but one auricle and one ventricle. Other cases nearly similar have been met with. It would appear, therefore, that very ample communications between the right and left sides of the heart, conditions which we should say admitted of the freest admixture of the black with the bright blood in the heart, occasionally occurred without cyanosis being the consequence. Some have therefore maintained that the essence of cyanosis consists in a stasis of blood in the capillaries of the body generally, and not on any admixture of unoxygenated with oxygenated blood.

I find it difficult, for my own part, to agree to this without some limitation; the livor in cyanosis is not precisely of that kind which we observe in connexion with impediments to the access of venous blood at the heart; in cyanosis there is no unusual development of the minute blood-vessels and intermediate vascular rete; the livor is precisely that of asphyxia, in which we know that black blood is circulated. Nevertheless, it must be confessed that the pathological condition which has been found accompanying most of the cases of cyanosis that have been recently examined has been, not a patent condition of the foramen ovale, or imperfection of the inter-ventricular septum, but a dilated and thickened state of the right cavity of the heart. Organic affections of the right side of the heart occurring in riper years are particularly, and at a very early period, proclaimed by a livid or violet colour of the face and extremities. The systemic venous circulation is greatly under the control of the right side of the central organ of the circulation, and implication of this is always accompanied by a retarded movement in the capillaries—hence the blue colour of the skin. The only explanation that could be given of the absence of cyanosis in those cases in which imperfections of the auricular and ventricular septa have been discovered, would be grounded on the accurate maintenance of the proportion between the powers of each side of the heart, and the resistance which it has to overcome. The

tension upon every part of the vascular system, I apprehend, must be the same; and as streams of like magnitude meet and roll their tides for many miles without mixing, so may the tides pertaining to the right and left sides of the heart be forced along their appropriate channels without becoming commingled in the heart.

With regard to the *treatment* of cyanosis, this must be entirely palliative. We cannot hope to remove by any medicine the organic imperfections or lesions on which it depends. Still, from what I have already said, it will be seen that no case should be abandoned as utterly hopeless. In infancy unusual care is required; engendering caloric less abundantly than other infants, the blue child is to be kept wrapped up in blankets frequently warmed, and should be supplied with the only nutriment that is adapted to its tender age, made additionally tender by its disease—mother's milk. By and by the food should be unstimulating, but nourishing, and never given in large quantities at a time. In the paroxysms of dyspnoea that are so distressing in cyanosis, after the first years of life have been passed, we sometimes feel strongly tempted to abstract a little blood; and, indeed, to relieve the labouring ventricle, we are sometimes forced to have recourse to the lancet. But this should always be done with great discretion; the loss of blood in such circumstances is ever followed by great prostration. Absolute repose, cool air, the application of cloths dipped in cold vinegar and water to the region of the heart, cold drinks or ice internally, and some sedative, such as hyoscyamus or opium—digitalis is too tardy in its action to be of service here—generally suffice to allay the paroxysm. When the disease towards its termination is attended with dropsical effusions, particular attention must be paid to the action of the bowels and kidneys; diuresis is less depressing than purging, and, therefore, preferable to it. When the strength is greatly reduced and the circulation extremely languid, we have recourse to tonics and even to direct stimulants, such as ammonia and wine, to keep the heart moving. This system of medication of course can only be pursued for a time; the powers of life fall lower and lower by degrees,

and the organs finally failing to be influenced by our stimulants, they cease entirely from their functions, and the patient is lost.

Inflammation of the heart, and of its internal and external investing membranes—Carditis, Endocarditis, and Pericarditis.

Carditis, Myocarditis.—There can be no doubt of the occasional though rare occurrence of inflammation of the muscular substance of the heart, apart from implication either of its external investing or internal lining membrane. It is infinitely more common, however, to find distinct traces of inflammatory affection of one or other, or of both these serous coverings, along with evidences of inflammation of the proper substance of the heart. Corvisart believed that carditis could not be distinguished during life from pericarditis, and Laennec maintained that carditis had never been observed otherwise than in connection with this disease or with endocarditis. We have, in fact, no signs pathognomonic of carditis existing *per se*. Unfortunately, in that which is held to be one of the most satisfactory instances on record of acute inflammation affecting the entire substance of the heart, the disease was complicated with an affection of the brain, which probably masked the symptoms, or at all events called off attention so completely from the central organ of the circulation, that the changes which it was found to have undergone in consequence of acute inflammation were not once suspected during the life of the patient. The particulars of this case may be found recorded at length in the seventh volume of the *Medico-Chirurgical Transactions*, by Mr. Stanley. The subject of it was a boy, twelve years of age, belonging to Christ's Hospital. He was apparently well on Saturday, April the 20th, after having visited one of his relations. Next morning, Sunday, April the 21st, he was brought to the infirmary of the establishment extremely ill. The symptoms were those of general acute fever; the skin was hot; the pulse was quick; the tongue was dry, &c. On Monday the fever had increased in intensity. The only pain complained of, however, was in the left thigh and knee, and had ceased before night. In the afternoon

he became affected with delirium, and had no sleep during the ensuing night. On Tuesday the delirium still continued; the pupils were dilated, and did not contract under the influence of light. The patient still made no complaint of pain; but when pressed on the subject he pointed to his forehead. In the afternoon he had a convulsive fit. Every symptom became greatly aggravated. The night was passed as usual without sleep. On Wednesday morning the patient was greatly exhausted, and the breathing was now for the first time observed to be difficult. He was sensible in the morning, but sank into a state of insensibility as the day advanced, and continued to decline till two o'clock in the afternoon, when he died. He had never complained of pain in the chest, and no irregularity had been noted in the action of the heart or pulse at the wrist. It is not stated particularly that the chest was examined; the stethoscope was not then known. On examining the body after death, the skull was found very thick and heavy; the bones showed no diploe, but were dense and solid throughout. The sutures were obliterated. The vessels of the brain were congested, but not in a very striking degree. In the thorax, the lungs were healthy. On laying open the pericardium, it was found to contain between four and five ounces of turbid serous fluid, with flakes of coagulable lymph which floated through it. The internal surface of the pericardium, both where it constitutes the containing pouch, and where it is reflected upon the heart, was covered in various places with a thin layer of lymph, having a reticulated appearance. The heart itself was natural in point of size, but upon cutting into its substance the muscular fibres were found exceedingly dark coloured, almost black, and very soft and loose in their texture, easily separable, and readily crushed between the finger and thumb. On looking attentively at the cut surface of the ventricles numerous small cells full of dark-coloured pus were visible in distinct points among the muscular fibres. Some of these points of pus were situated deeply near the cavities; others lay more superficially, so as even to raise the reflected pericardium. The muscular fibres of the auricles were likewise soft and dark coloured, but

they did not appear to contain any purulent points. The endocardium was judged to be healthy, as were the valves, save that the vascular ramifications upon these parts were more distinct than usual.

This case is frequently referred to in works on diseases of the heart; but, strange to say, it is seldom quoted correctly. Dr. Latham, for instance, citing it as a case of disease of the heart simulating disease of the brain, says, "not a vestige of disease was found within the cranium." But I have quoted immediately from the reporter, and shown that he speaks of congestion of the brain, and of an eburneous state of the skull, with obliteration of the diploe and sutures; a state which very certainly cannot be called healthy in a boy of 12 years of age. Neither is there generally any mention made of the evidences of inflammation of the pericardium which were discovered; the case after all was not one of pure carditis, but of carditis complicated as usual with pericarditis.

In discussing the symptoms of carditis, we are reduced to indicate phenomena which from analogy we should anticipate, rather than able to speak of any which have been positively observed. Where the attack is slight, it is presumed that there would be pain of greater or less severity, and in all probability occurring suddenly in the region of the heart; disturbance in the action of the heart, at first violent, but speedily becoming feeble, (for the invariable and very rapid effect of inflammation affecting the muscular substance is to paralyse it), and as in all inflammatory diseases, the symptoms of general fever. The attack being graver in its character would be marked by the occurrence of pain of a severer description, of an oppressive and stringent kind, referred to the heart; by violent palpitation, tumultuous and irregular action of the heart, accompanied by a sense of anguish, of alarm, and of imminent dissolution. I cannot imagine that any peculiar bellows sound need necessarily accompany the disordered action of the heart in simple carditis. The pulse at the wrist under such circumstances can only be expected to have volume and power in the very beginning of the attack; it would soon become small and fluttering, and be unrhythmical, in accordance

with the character presented by the action of the heart. The respiration would be accelerated, but not otherwise peculiarly affected, unless congestion of the lungs were superinduced. The alimentary canal, save in connexion with the general pyrexia, would not be affected. The extremities would be cold; the expression of countenance, as in heart diseases of the gravest kind, would be that of great distress. The functions of the brain and nervous system would appear occasionally to be very seriously implicated in carditis; delirium, convulsions, and coma, have been indicated as frequent sympathetic consequences of the disease. Carditis would, in fact, appear occasionally to have existed, and even gone on to a fatal termination, altogether unsuspected, because of the severity of the symptoms referable to implication of the brain. Both M. Andral and Dr. Latham have given cases of fatal cardiac and pericardiac disease, where during life the symptoms were all referred to the centre of the nervous, not of the circulating system; and in a remarkable instance, which I have quoted after the report of Mr. Stanley, the same circumstance occurred. In one of M. Andral's cases there was delirium, general convulsive movements, and twitchings of the tendons, for three days; on the fourth day the delirium ceased, but the convulsive motions continued, and the arms were from time to time thrown into a state of positive tetanic spasm. On the fifth day the delirium returned, and the upper extremities became paralytic. The patient then fell into a comatose state, and died. On dissection neither the brain nor the spinal marrow, nor the membranes, presented the slightest trace of disease; neither did any other organ of the body, except the heart, show evidences of having been the seat of morbid action. Upon the surface of the pericardium, however, there was a copious deposit of lymph, and into its sac an effusion of serous fluid. So also in a case of acute rheumatism, which was under the care of Dr. Latham, in St. Bartholomew's Hospital, the whole force of the treatment was directed to the head, under the impression that the brain was inflamed, the symptoms being those that usually accompany and proclaim phrenitis. Upon dissection, however, the brain

adviser, alarmed by the smallness and want of rhythm in the pulse, neglects venesection in the earliest period of the disease! If this fatal error be committed, all else will be in vain. Blood-letting is the only means that can be relied on, the only remedy competent to cut short so formidable a disease as carditis, whether its immediate tendency, or its consequences, should it not destroy the patient at once, be considered. General blood-letting, then, in the first instance, followed by local depletion, each repeated again and again in proportion to the violence of the symptoms rather than the estimated strength of the patient, is what we have to rely upon for the cure of inflammation of the heart. Along with this powerful means it is at the same time proper to call in the depressing effects of antimony and opium, or digitalis, and, farther, to use every effort to get the system under the specific influence of mercury, administered by the mouth and by inunction simultaneously. The patient should of course be kept in a state of the most perfect quietude, and allowed nothing but a little cold or iced drink to quench thirst and allay excitement.

[To be continued.]

EFFICACY OF CARBONIC ACID GAS IN GOUT.

To the Editor of the Medical Gazette.

SIR,

IN a work that I recently published, with the express object of recommending a particular remedy for the cure of that intractable and painful malady, gout, it was stated that, as far as my experience went, the remedy in question—carbonic acid gas—shortened the paroxysms, and lengthened the intervals of the attacks, to a greater extent than any other with which I was acquainted; so that attacks, which before lasted two or three months, were reduced in the end, and after the lapse of some years, to as many weeks or days; while the disease itself, instead of returning twice or three times every year, was only experienced every second, third, or fourth year. Two cases only were then given as illustrative of its efficacy; one shewing the effect of the medicine during the paroxysm, and the other its ultimate result. I was in

hopes, however, that some of my professional brethren would, ere this, not only have given the remedy a fair and proper trial, but, at the same time, have been induced to make the result of that trial public; for it was in this hope and expectation that I published the work in question. Being disappointed, however, in this respect, and having received several private communications on the subject, I have selected the following case, from among several others, thinking that it may not be uninteresting to the readers of the *MEDICAL GAZETTE*. The particulars were forwarded me a short time since from Barcelona, where my work is about to be published in Spanish, Dr. Fritz being now engaged in translating the same.

The writer is an English gentleman, who, having experienced an attack of gout last spring, wrote to me for directions respecting his own case, and subsequently for that the history of which I am about to relate.

After speaking of the satisfactory state of his own health, the writer thus continues:—"You must know, then, that your remedy appears to have effected a *radical cure* in the patient, who has been under our care since last June. It is such a striking case of the success of your treatment, that it really deserves to be added to the work; and I regret very much that I am so little qualified to draw up a report for that object. I could, however, get something like a deposition from the patient, attested by respectable witnesses, if such a document could be of any service in making known the wonderful effect of *carbonic acid gas*.

"The person in question (a Spaniard) is about 40 years of age, and has suffered very severely for about fifteen years with three or four attacks every year of the most severe kind; the disease generally commencing in the hands or feet, and extending itself to the elbows, knees, shoulders, &c.; and on one occasion to the testes. He describes the agonies he used to suffer as so great, that he has frequently called on those about him to put an end to his existence. His fingers are distorted and crooked; and, in short, although it may be an improper remark on such a serious subject, he went by the nick-name of 'Commander of the Gouty Legion.'

"The draughts (effervescing) were administered to him, in the first instance, at the onset of an attack in the right hand, brought on, as he supposed, by a fit of passion the preceding day. The inflammation subsequently reached the elbow, but went no further. He complained, however, of the pain this time being even greater, if possible, than he had ever suffered; and, being an ignorant man, had got it into his head that it was owing to the disease not being able to spread as usual, by which all its malignity was concentrated in one spot. I made him take the draughts every three hours, supplying him out of my own stock of French soda, not trusting to the Spanish, which, you know, is inferior. In three days he came round, the violence of the pain and inflammation having entirely subsided; after which he only took the draughts three times a-day, until all symptoms of the attack had disappeared.

"After this he continued quite free from the disease for three months, when symptoms of another attack were felt; but, full of belief in the efficacy of the remedy, he passed the first or better part of the night in taking a draught every two hours, or even more frequently, till at last sleep overcame him; and when he awoke late in the morning every symptom had disappeared, and he found himself as if he had been dreaming, and quite well. From that time down to the present day (now five months), he has had no signs whatever of the distemper.

"It is right to state that, in addition to the effervescing draughts, I advised the patient, as soon as the intensity of the attack had subsided, and the inflammation had partially disappeared, to take a few grains of blue pill every other night, and in the morning an electuary, composed of sulphur and magnesia—a prescription I have found to suit the irritable and weak bowels of gouty subjects better than most others. When the latter combination was not found sufficient, an aloetic preparation was recommended to be added to the blue pill, and a slight aromatic tonic during convalescence."

In closing these remarks I am bound to add, that the result obtained in so old and severe a case would appear to be greater than that which I have myself hitherto experienced; and I am

induced, therefore, to ascribe the difference to a circumstance that has been before dwelt upon by me, viz. that in Spain many diseases are milder and less complicated than in this country*. Not that I concur in the opinion expressed by the narrator of the present case, that a radical cure has been effected, if, by radical cure, be meant a total exemption in future from attacks of the disease. Such a result ought not, and cannot be expected; for if the remedy in question acts only, as I presume, by removing the cause—no matter what that cause is, whether external or internal—the individual must always be liable to be again brought under its injurious operation, the same as before the first attack of the disease. If, however, gout be produced, as I infer, from the presence of a morbid matter in the blood; and if, as I still further conclude, we possess an agent capable of combining with it, and rendering it innocuous, all that we require is a certain amount of time, (varying, of course, according to the severity of the disease), and the duration of the attack and recovery of the patient, instead of depending, as heretofore, on the efforts of nature, or the as uncertain efforts of art, may then be calculated on with something like a certainty; while the attacks themselves, instead of continuing for months, and returning two or three times every year, will only be experienced once in two or three years, and then only continue for a few days or weeks. I, of course, except those cases, too frequent, alas! in which structural or organic alteration has taken place in any vital or important organ, produced not only by the injurious but the long-continued operation of a cause, that the science of medicine has hitherto been unable to remove with certainty and with safety.

Trusting that the history of the preceding case will prove interesting to the readers of the *MEDICAL GAZETTE*, and that the result of the treatment may induce some of your numerous subscribers to give the remedy in question a fair trial, I have only to add that, whatever the result of the trial may be, it will, I hope, be made public; not for my satisfaction, but for that of a large class of sufferers who,

* Vide *Lancet*, May 12, 1838: On the State of Medicine in Spain.

at present, are too generally sceptical of the efforts of art in the cure of their complaint.—I am, sir,

Your obedient servant,
J. PARKIN.

18, Dover Street, April 3, 1843.

SEVERE AFTER-PAINS FOLLOWING LABOUR,

TREATED SUCCESSFULLY BY BELLADONNA PLASTERS.

To the Editor of the Medical Gazette.

SIR,

SHOULD the following case be deemed sufficiently interesting, its insertion in your columns will oblige, sir,

Your obedient servant,
ROBERT NIXON.

Wigton, April 1, 1843.

Mrs. B., aged 28, a lady of cultivated and lively turn of mind, but of a marked leucophlegmatic temperament, and who had experienced a severe hysteric seizure, the consequence of prolonged uterine hæmorrhage during a former puerperal confinement, was taken in labour on the 27th of October, 1842, of her third child, which was born with comparatively trifling suffering. The placenta came away spontaneously, and all went on favourably until the morning of the 29th, when the after-pains, which had previously been slight and not frequent, became so distressing, that a table-spoonful of the following mixture was ordered every half-hour till relieved.

℞ Solution. Morphine (equal to Laudanum)
ʒiv. ; Aquæ Destillatæ, ʒiiss.

Nine hours elapsed ere I could again visit my patient; and notwithstanding that the morphia had been persevered in, the lady's pains were much increased. Tossing in bed, she caught at every thing for a fixed point to cling by; her moanings were heart-rending; her countenance anxious, and indicative of great suffering; the pulse, naturally feeble, was hurried and thready, and the extremities were cold. Some hot brandy and water was given; friction, hot water, and stockings filled with heated salt, were applied to the legs and feet. A starch enema was substituted for the anodyne mixture, containing a tea-spoonful (ʒiiss.) each of laudanum and solution

of morphine, and was repeated every half hour until nine had been given, and they were all retained. Thus gr. v. of morphia were taken into the stomach, and an equivalent to gr. xvj. and a fraction passed into the rectum, without the slightest alleviation to her dreadful agony, the pains continuing as obstinate as before. Laying aside other remedies, I now covered the entire hypogastric region with a belladonna plaster, made by spreading the extract thickly upon linen, and waited the result. In an hour and a quarter the pains were much diminished in violence, occurred at longer intervals, and finally altogether ceased; but she complained of a prickling sensation over the body, especially the face, across which she rapidly, apparently involuntarily, passed her hand. The plaster was now removed, and some time afterwards she complained of the closeness of the apartment, and was obliged to be fanned. Suddenly she started up in bed, gasping and shivering most violently. A wine-glassful of brandy and water happening to be at hand, she drank it with difficulty and danger of breaking the glass from spasmodic action of the muscles of the jaws and face. Active friction was again made use of to the hands and feet, which were still cold; a few tea-spoonfuls of very strong coffee having been given, in about twenty minutes she expressed herself better, and quietly laid down in bed, when gentle perspiration came on, and was succeeded by five hours' sleep. She awoke in the morning much refreshed; but during the day there was a return of the after-pains, which, towards night, became more severe. Bladders, partially filled with hot water, were applied over the womb for about two hours, when they were gradually mitigated, but recurred at intervals for several days afterwards. Slight hæmorrhage was observed after the application of hot water, which continued about a week, and materially contributed to reduce the sufferer, who, however, was convalescent in four weeks.

REMARKS.—It may be asked, why not have had recourse to the application of hot fomentations when the failure of morphia was clearly ascertained? The dread of inducing hæmorrhage, the effects of which had

nearly proved fatal to the lady during a previous delivery, alone deterred me. The result of the experiment made in the present instance, when a relapse occurred, sufficiently points out the danger of such a procedure. With the concurrence of my experienced friend, Dr. Rigg, of Woodrow, I was induced to follow up the exhibition of morphine and laudanum until 21 grains of the salt were administered, as already detailed, without the slightest manifestation of change, the intensity of the pains being in no degree abated. The relief afforded by the application of belladonna was very decided, and contrasted strongly with the inadequate powers of opium and its preparations. Indeed, the marked success witnessed in this instance, without presuming too much upon an individual case, warrants me in recommending a further trial of it by the profession, believing it may become a powerful auxiliary in the treatment of this extraordinary kind of after-pain, fortunately not often met with in these latitudes.

What is the pathological condition of the uterus, which either completely nullifies the effects of poisonous doses of morphia, or apparently in precisely similar circumstances allows this organ to be brought under its immediate control by very minute quantities?

NOTE.—I may mention the solution of morphia was prepared from the muriate manufactured by Mr. M'Farlane, of Edinburgh.

INTRA-THORACIC TUMOR.

To the Editor of the Medical Gazette.

SIR,

As the subject of intra-thoracic cancer affords at the present time an interest to your readers, from a case lately related by Dr. Maclachlan, allow me to offer you some account of a similar instance of that disease—no less terrible to the patient, than, when observed for the first time, it is puzzling to the practitioner.

Having mislaid my notes, made during the progress of the case, I am under the necessity of writing from memory; and although, from this circumstance, I cannot undertake a very particular description of the advent and march of the symptoms, these are, from the in-

tense suffering of the patient, which I never can forget, and from the speculation they excited in my own mind in reference to their probable cause, sufficiently imprinted there to enable me to give a true though brief sketch.

I think it better to divide my description of the case into three parts; not that such a division is warranted by any change in the character of the disease itself, which is uniform and progressive, but because, in proportion as it advanced, it encroached upon important organs, and thereby impressed the aspect of the case with new features and distinct points of interest.

M. L., male, æt. 45, with dark hair, pale complexion; of square build, muscular, with well-developed chest, and always having enjoyed good health, was attacked, in the year 1838, with severe intercostal neuralgic pain of the right side. This was considered to be rheumatic, and was treated accordingly, with apparent benefit. The patient had many relapses of the pain, but being much exposed to draughts, and the damp atmosphere of a chilly season, no surprise was occasioned.

In this first division of the case, the nerves only were embarrassed. In the second the respiration and circulation became affected; for there were cough, dyspnoea, rapid pulse, and hæmoptysis; the physical signs elicited being partial suppression of the respiratory murmur, and dulness of sound on percussion. At this period the opinion of the late Dr. Thomas Davies was sought, which, though not explicitly conveyed to me, I judged, from the character of his prescription, and the tenor of his directions to the patient, that experienced physician considered the case one of tubercular degeneration or hardening of the lung.

In the third stage the pain and cough were almost ceaseless, and the hæmoptysis more frequent and abundant. The right side of the chest was enlarged, distended, and immovable. The respiratory murmur, last heard about the scapular region, could now nowhere be detected. The sternal region was insonorous, as also was the subclavicular region of the *left* side. The apex of the heart was observed pulsating two inches to the left of its original position, and the edge of the liver was felt some distance below the costal margin. There was general

venous congestion, marked by a livid surface, distended jugulars, immense hæmorrhoids, and anasarca, more especially of the face and upper extremities.

The patient died suffocated in about five or six months from the first attack of neuralgic pain.

Post-mortem appearances.—The sternum and cartilages of the ribs having been removed, an immense tumor was exposed, entirely filling up the right pleuritic cavity, both mediastina, and the upper third of the right pleuritic cavity. It was everywhere firmly adherent, except where intruding on the left side. It was a fine specimen of "medullary sarcoma," consisting of hard, irregular, scirrhous portions and septa, inclosing lobulated masses of various size, and of brain-like appearance and consistence. It must have weighed from twelve to fifteen pounds. On removing it from its bed, the remains of the lung were found adhering to the posterior wall of the chest, compressed to the exclusion of all air, and about one-third of an inch only in thickness. From this latter circumstance, and from its apparently complete immunity from cancerous disease, I was led to consider the case one of cancer of a bronchial gland.

Your obedient servant,
WILLINGTON CLARK.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

LUNATIC ASYLUMS IN ENGLAND AND IRELAND.

DR. HARTY, on whose pamphlet we touched a few weeks ago, is fertile in objections to the Act passed last session for the regulation of lunatic asylums in Ireland. Many of his censures are well founded, the Act having been so hastily passed as to be frequently inconsistent with itself; while others are eminently hypercritical, and could scarcely be obviated, unless we

repealed not only Acts of Parliament, but human nature itself.

Thus, "Section 7 enacts, that the license shall be signed by *two* or more Justices, while Section 5 says, that it shall be under the hands and seals of *three* or more."

This is a gross inconsistency; but to show how easily even critics may err in a matter of figures, we will just mention that two pages afterwards, Dr. Harty himself dates a letter September 20th, 1843.

Again, while the English Act ordains that no person shall be received into a licensed house without a written order from the person sending the patient, and two medical certificates, the Irish Act adds the words "or detained" after "received."

It is obviously desirable that certificates should be renewed from time to time, and that no man should be indefinitely detained on the strength of an old certificate; but from the imperfections incident to Acts passed in August, a literal compliance with the requisitions of the statute is impossible. Thus it is enacted that the order for the detention of the patient shall be under the hands of the person by whom he was originally sent; whereas, in many cases, the original applicant has gone to that bourne from which no signatures can be sought.

We will not do more than mention a certain Schedule (H.) rich in blunders from beginning to end; nor will we insist on the fact, that while in Ireland the penalties imposed by the Act may be recovered by any person who sues for them, in England the transgressor is protected against common interlopers, for no suit can be brought under the Act, except by order of the Commissioners, or Justices, nor can penalties be sued for except by the Clerk of the Commissioners, or the Clerk of the

Peace. Dr. Harty thinks the Irish Act too severe on Irish offenders; perhaps, it is the English Act which is too hard upon English lunatics. From Dr. Harty's observation on the machinery of the Act, we learn that the Irish proprietors of lunatic asylums are a very different class from those of England. It appears that in the extra-metropolitan districts of England and Wales, "of 85 houses, containing nearly 3000 inmates, many are kept by women, and 30 only by members of the medical profession; and from the second return, embracing the metropolitan district, it appears that of 41 houses, containing upwards of 2000 inmates, six only were kept by physicians; whereas in Ireland all the proprietors of private Asylums are physicians, with two exceptions only, one being an apothecary, and the other a gentleman not professional."

Dr. Harty very reasonably proposes that if an asylum has but one proprietor, he should always be a member of the medical profession; or, if there are several, that one at least should have this qualification. For, since an asylum is an hospital for the cure of patients who want medical treatment, it is obviously absurd to neglect so great a step towards the thing required. In an asylum where the patients do not exceed ten in number, both the English and Irish Acts allow them to be visited by their medical attendant as seldom as once in four weeks! These "angels' visits, few and far between," may satisfy the law, but will be highly inefficient in physic. Dr. Harty attributes this inconsiderate legislation to the strange evidence tendered to select committees, and received by them, he says, "almost without comment." Now, the fact is, that select committees, like all other collectors of evidence, are obliged to take it as it is to be found, *i. e.* with an ample leaven of spleen, ignorance, and

exaggeration; did they refuse to hear any but philosophic witnesses, their labours would be brief indeed. It is their business, *ex Ennii stercore aurum colligere*; to separate golden suggestions from the rubbish in which they lie buried, and extract something valuable even from the anger of Mr. Edward Wakefield. This noted land-agent had a prejudice against our profession, amounting, as we should now say, to a monomania; for, in his evidence before the Committee of 1815, he fancied that medical practitioners, and particularly the College of Physicians, were, of all persons, most unfit for inspectors of madhouses. This singular delusion, however, did not prevent the Committee from separating a portion of *aurum* from the *stercus*, and the improved state of madhouses is, no doubt, due, in some degree, to the zeal of this ardent reformer. We do not think, however, that the rareness of medical visits permitted by the legislature at the smaller asylums arises from Mr. Wakefield's hallucination, but rather from a disinclination to deal harshly with vested interests. As every lunatic asylum is an hospital, a practitioner ought to reside in each and every one; but as the profits of the smallest asylums could not afford the expense, such an enactment, though just in itself, would be equivalent to an Act for the abolition of small madhouses. There is one point, on which Dr. Harty touches more than once, which can never be cleared up till lawyers and doctors can define the limits of eccentricity and madness—in short, can measure metaphysical difficulties with mathematical nicety. Till this be done, there will be many men at large whom some of their neighbours pronounce to be mad, which is surely better than that others should be confined whom their neighbours believe to be sane.

An M.D., however, who is on the confining side of the question, writes a long letter to Dr. Harty, complaining of the difficulty of immuring a supposed monomaniac, whose case he details. This eccentric gentleman forms wild speculations, and obtains money on the strength of these castles in the air, which he spends in drink and driving. In the words of the discontented M.D., "he is seized at times with the most irresistible desire for rapid motion, and will hurry about in all directions on hired cars, without any definite purpose." Even the sober Dr. Johnson thought hand-driving in a post-chaise the finest thing in life, and, in our age of railways, we cannot accept a love of rapid motion as a proof of insanity*. But the most curious complaint in the letter is, that the monomaniac carries the new Act about with him as his safeguard. On us this makes a different impression. In Ireland, where the bludgeon and the blunderbuss are the common referees on all occasions, and the still small voice of reason can scarcely be heard amid the cries of party, it is cheering to see an insane man appealing to parliament for protection, and asking no other ægis but the law.

We might comment on some other points in Dr. Harty's useful essay, but our limits warn us to pass on to the pamphlet which we alluded to in our last article on this subject; we mean the Report of the Visiting Justices of the Surrey Lunatic Asylum.

Springfield Asylum, which is a very handsome building, is situated between Wandsworth and Tooting, and is capable of accommodating upwards of 350 patients. Its total cost, including the

* We have sometimes thought that a railway is a poor man's hunting field, where he may enjoy the pleasures of the chase, namely, rapid motion, with a spice of danger, at a trifling expense. The absence of a fox, which is to be killed, or a stag, which is not to be killed, can make no material difference.

purchase of land, furniture, &c. was £85,000. It was opened in June 1841; and the number of patients admitted up to September 23d, 1842, was 389. Restraint, though not wholly abolished at the Surrey Asylum, is but rarely resorted to. Omitting the confinement of patients to their bed-rooms, which, in this Report, is called restraint by seclusion, the whole number of patients restrained, from January 1st to September 23d, 1842, was but 11. Four of these had extensive sloughing sores, and their hands were bound by handkerchiefs to prevent their taking off the poultices, and irritating the sores. No strait waistcoat appears to have been employed in any case. The Committee, who say that they feel the importance of obtaining respectable and trustworthy attendants, assert that their remuneration has been fixed on a liberal scale. On turning, however, to table iij. we find that, of nine female attendants, three have £16 a year each, three £15, and three only £12. These salaries are less than the wages of upper servants in private families, and, in fact, less than what is given to the cook, bakeress, and laundress, in this very establishment. Considering the immense power for good and for evil of the nurses in a mad-house, this is certainly a false economy. As their remuneration is to increase annually during the first five years of service, this error will be mitigated, but, we apprehend, not entirely remedied.

The average number of males employed has been sixty-three; of females, ninety-two. The former have been employed in the garden, the farm, their several trades, the kitchen, and the wards; the latter in the laundry, kitchen, sewing, knitting, straw work, and the wards.

One hundred and twenty-three patients, on an average, have attended chapel.

Nor is amusement for mind and body forgotten.

"In the way of recreation, a bowling-green has been prepared, and a library commenced, which already contains about eighty volumes of useful and entertaining knowledge, together with the Saturday and Penny Magazines, and Chambers' Journal; draft-boards, and other means of amusement, are permitted; and the patients are indebted to the kindness of a member of the Committee for a pianoforte, which has been a source of much pleasure."

We will conclude by mentioning a useful and benevolent provision. The visiting Physician furnishes patients, on leaving the Asylum, with such rules as he considers best adapted to prevent a relapse. Sir Alexander Morison, fills this office.

TWO CASES

OF POISONING BY LEAD, IN MACCUBA SNUFF.

COMMUNICATED BY PROFESSOR OTTO, OF
COPENHAGEN.

Two cases of poisoning, probably by Maccuba snuff containing red lead, have excited universal attention in Copenhagen. In the spring of 1842, M. Dreyer, highly esteemed as a scholar and botanist, died there after four months' illness, the symptoms having been doubtful, and their cause difficult to ascertain.

The deceased was much lamented, but his death had been almost forgotten, when his friend Dr. Bramsen read in a journal that red Maccuba snuff was sometimes adulterated with red lead. On this, he imagined that his deceased friend, who took a great deal of this snuff, might have been poisoned by it. He therefore bought some at the shop where the deceased used to buy his, and found that it was mixed with a number of large and small grains, which looked like minium; and, on chemical examination, he discovered that the snuff contained from 16 to 20 per cent. of lead.

After this discovery, Dr. Ahrensen, the physician of the deceased, did not doubt that Dreyer had been killed by the lead contained in the snuff; and this opinion seems

fully confirmed by the course of the symptoms.

The patient, who was always rather pale, but who had almost always been well, with the exception of some unimportant chest symptoms, fell ill in the autumn of 1841. He had the common symptoms of dyspepsia with costiveness and a muddy complexion. As he lived a sedentary life, and devoted himself with great diligence to scientific pursuits, exercise was advised, and bitter and laxative pills were described. After this, he felt a little better, when, a few days before Christmas, he was suddenly attacked by violent colicky pains, which made him scream loudly, and throw himself from one side of the bed to the other. The pulse was natural, the tongue clean, the abdomen normal on percussion, and not painful on pressure. The bowels had been open the day before. The laxatives which had been prescribed were omitted; but some clysters, containing a grain of opium, diminished the attacks, and at last removed them entirely. The course of the symptoms, the effect of remedies, and the absence of all indications of disease in the viscera of the abdomen, excited, even then, suspicions of lead colic; and it occurred to Dr. Ahrensen that the red wine which he had recommended the patient, and which was very cheap, might possibly contain lead; but the examination of the wine, as well as of the vessels in which the patient's food was prepared, gave only negative results.

His improvement was of short duration; evacuations from the bowels were extremely rare, and when there had been none for a couple of days, from the omission of the medicines, the colicky pains returned, combined with cardialgia, and sometimes so violently, that the patient seemed to be in the greatest danger. He had four of these attacks during the winter, which were removed, partly by cathartics, partly by opiates. In one paroxysm alone, the pulse was rather quick, and somewhat tense, and the abdomen tender on pressure; so that Dr. Ahrensen, to face the possibility of an inflammatory complication, bled once, and added calomel to the opium. As he could not discover any other cause for the symptoms, he supposed that a stricture of the colon existed, as well as a dilatation above it; a supposition which was confirmed by the evacuation of a large mass of round hard feces during the last attack, after which the patient felt pretty well. Though he had become very thin, and his complexion was still dull and yellowish, he now began to attend to business; but, a week afterwards, he was suddenly attacked by violent headache, which he ascribed to catching cold. Dover's powder, and elder tea in the evening, relieved him on the following day, but in the

afternoon the attack returned with increased vehemence, and, as the pulse at the same time decreased in frequency, and he fell into a comatose state, it could no longer be doubted that the brain was attacked. After being fruitlessly treated with leeches, blisters, and strong purgatives (croton oil), he was taken to the hospital, where the symptoms remained unchanged, and were terminated by death two days after his admission, six days after the commencement of the cerebral affection, and about four months after the first attack of colic.

On dissection, nothing abnormal was found in the abdomen, except a trifling enlargement of the colon, probably caused by the frequent clysters; the brain, too, was healthy, except a slight injection of the membranes.

The striking resemblance of the first symptoms of the disease to lead colic, the agreement of the cerebral symptoms with those which occur in the comatose form of the *Encephalopathia saturnina* described by Tanquerel de Planches, the negative results of the dissection, and the patient's almost constant complaints of colicky pains, which were present during the whole course of the disease, make it highly probable that the fatal event was caused by the adulteration of the snuff with red lead.

These circumstances have made the case of another patient, a young physician, who is still alive, very conspicuous. He has suffered for a year from an affection of the abdomen, characterized by colicky pains and obstinate costiveness. during which he has become extraordinarily thin. This patient is also a great snuff-taker, and long used the same snuff as the deceased patient. As he has now left it off, it is to be hoped that his malady will be cured. The tobacconist has been cited to answer for his misdemeanor. —*Zeitschrift für die gesammte Medicin*, March 1843.

MEDICAL REFORM.

To the Editor of the Medical Gazette.

SIR,

SOME months have now elapsed since my last letter to you on the subject of medical reform*. This delay, which has been almost unavoidable on my own part, is of the less consequence, inasmuch as it was generally known that the last session of Parliament would be closed without any measure being adopted for the alteration of our professional constitution.

The basis on which I had proposed to form the whole medical profession consisted of three corporate bodies—two already in existence.

1st, The College of Physicians,

2d. The College of Surgeons, and the

3d, A College or Society of Pharmacy.

This division of the profession I endeavoured to show was founded on the *nature* of our occupations, and calculated by certain combinations of their diplomas to meet every necessity arising out of the application of its services to the public good.

It remains now to be considered how this plan might be carried out; which, supposing it to meet the approbation of the majority of the profession, would be of no great difficulty in its accomplishment.

The Colleges of Physicians and Surgeons being already established, it would only remain so to alter and enlarge their statutes as to meet the case. The establishment of a new Society or College of Pharmacy, with appropriate charters, would not be difficult; and indeed the efforts of many of the best and most respectable chemists of the present day have long been tending in that direction.

So far as regards doing: but there remains one little task of undoing: would that all reformers could be persuaded to allow their undoings to bear an equally small proportion to their doings! To this plan of medical reform the Company of Apothecaries, as a Company, must yield—must cease to exist! It is probable that a greater resistance to this proceeding would be made by the ruling powers amongst this Society than by the members generally. To these gentlemen, therefore, I would say most respectfully, as well as most sincerely, that I am by no means insensible of the debt of gratitude we all, as a public, owe them for their past services and zeal: to them, in great measure, we owe it that the general practitioners of later years have been so much higher in character, and so much better practitioners. But I need hardly remind them that it is the true characteristic of greatness to hold power no longer than it is required for the public good; so soon as the necessity ceases, so soon will a truly great-minded man yield his power. If, then, it can be shown to their dispassionate judgment that the usefulness, the comfort, and the high character of our profession, may be raised by their relinquishment of power, and the establishment of a different regulation of our profession, I need hardly remind them that it is their duty not only to resign that power, but cheerfully to cooperate in promoting the public good and the advancement of that profession of which they have been no idle ornaments: I would conjure them to consider the arguments adduced, and to be adduced, and especially those directed to the

* See MED. GAZ. for July 15, July 29, Aug. 26, 1842.

general mass of apothecaries of which they are the head.

To the general practitioners as apothecaries I would say:—You have been the loudest declaimers for reform! and with great justice. You have complained of want of protection both from the wolves within and without the sheep-fold. Those privileges which have cost you dear in time, in study, and in money, have availed you nothing. The impudent quack from without, the hungry foreign doctors, and the pert chemists, from within, have eaten the bread for which you have not only toiled but paid a premium.

It is evident, therefore, that the system under which you live avails you nothing; the body corporate which has been supported and maintained by your labours and your purse, has had no power to defend you in the enjoyment of those privileges which it professes to have given you. You complain, with justice, of an equivocal social position. When that portion of your youth which should have been dedicated to the acquirement of useful general knowledge has been devoted to a slavish apprenticeship to the pestle and mortar, how can it be otherwise? When, in after life, your usefulness as professional men, your improved manners from mixing with the world, your minds stored with no mean share of general knowledge, and probably with a vast knowledge of human nature, how can you expect to hold that position which your merits deserve? When, to the most beneficent and high-minded avocations of your profession, you add that of a retailer, if I may so say it, in drugs, and, instead of demanding from the wealthy that sum which your services deserve, you call upon him for payment for a draught, a powder, or a pill? If, then, this plan of reform were carried out, it would be only necessary that all members of the Apothecaries' Company should at once be registered as "*Members of the College of Physicians*," either gratuitously or on the payment of a small fee. As most of them are already Members of the College of Surgeons, they would incur no trouble of change as regards that corporation. In carrying out such a measure of reform I should strongly urge its being done with the utmost liberality to all existing qualified practitioners; and as there are at present several Members of the Apothecaries' Hall who, though practising upon no other qualification, have yet probably, with a just appreciation of their merits, obtained so high a share of public patronage and opinion, as, in fact, to assume the characters of physicians by practising for fees and in consultation, I would advise that the *Fellowship* of the College of Physicians should at once be offered to them on the payment of the proper fees. For the future,

however, no such irregularities should be allowed. I need not, of course, say that under this system of reform the *Fellowship* of the College of Physicians should at once be conferred upon such of its present Licentiates who may wish to continue their career as pure physicians; some might, perhaps, under these alterations, wish to fall into the order of general practitioners—such a change might be easily provided for.

As it is possible that in the first setting out of such a system of medical reform many existing general practitioners would be found unwilling to forego the profits accruing from the sale of drugs, it would be desirable that the Society of Pharmacy should, upon the payment of a smaller fee, admit such persons as members of their Society.

It now comes to be considered whether the College of Physicians should have the power of conferring degrees, as well as granting diplomas. I cannot see any direct good to be gained by this, and if it were granted to the College of Physicians it must also be granted to the College of Surgeons.

The power of granting degrees seems rather to belong to Universities; and I have before shown that a College of Medicine or of Law, or any one science or profession, cannot with propriety be called a University. The degrees of M.D., LL.D., D.D. of the Universities, implies, or ought to imply, that their possessors have undergone that general system of liberal education which is peculiar to these Universities with credit and respectability; but have more especially dedicated their studies to that branch of learning which such degrees imply. The degree of LL.D. probably, as less necessarily pointing out any professional distinction, is the one which is usually conferred as a distinction of honour upon eminent men unconnected with the universities.

As the prolonged course of study required of a person to enter the field as a physician affords a greater amount of leisure time, it is probable that the majority of those who commenced life as physicians would have obtained some university degree before becoming Fellows of the College of Physicians. This probability would be still further increased by the fact of their having to wait till a more advanced age before the acquiring any considerable amount of private practice. Latterly some few members of our English universities have entered the College of Surgeons; and it is likely that still larger numbers would enter it as Fellows of that College.

Again, the power of conferring degrees by the Colleges of Physicians and Surgeons might cause some little jealousy in the universities, a circumstance the rather to be avoided as the carrying out this plan of reform must necessarily demand a small sacrifice on their parts, which it is reasonable

to hope and expect they would willingly yield for the public good.

Hitherto the power of the College of Physicians, though nominally extended to the whole country, has been virtually limited to London and its environs; and even within these scanty limitations has been barely able to maintain its powers. Now, should the power of the College be extended, as appears to me most desirable, to the whole of England, it would require of the Bachelors and Doctors of Medicine, even of our English universities, to seek and obtain its diploma before they could enter into practice.

It may be said this plan of medical reform applies only to England; how are the difficulties with respect to Scotch, Irish, and foreign degrees to be got over? With respect to Scotland and Ireland I would answer, why not carry out there also the same measures? If not, for these and all other degrees, we have only to deal with them in this way. Our medical corporations require such and such an amount of professional education as a qualification for examination at their board. A candidate has only to bring certificates of such qualifications, and having creditably passed his examinations, will be admitted a practitioner. Failing to bring such qualifications, and not duly passing such examinations, he cannot become a qualified practitioner.

Much has been written and said on the subject of medical education. No doubt professional education is a subject of vast importance, both to the profession itself and to the public generally; but it is questionable in my mind, in a profession like our own, in which so much competition exists, and where individual success can only be fairly hoped for and expected in proportion to individual labour and exertion, whether professional education is not safer in the keeping of the heads of that profession than in a government, however well disposed and constituted. It is my humble opinion, therefore, that we only need the assistance of government to put our professional institutions on a proper footing, and to afford them that protection which is alike due to them and really useful to the community; and that we shall be found competent in ourselves so to regulate professional education as to send into the world a class of medical practitioners who shall, as a whole, richly deserve the gratitude and protection of the country, and do honour to the bodies corporate of which they are members.

Medical education, indeed, so far as the mere amount of knowledge is concerned, has of late years kept pace with the vast strides of the march of intellect. No great cry for medical reform has been uttered

throughout the country from without, on the plea of the ignorance and disqualification of medical men. No! the public are contented, and justly contented, with the amount of medical knowledge, and for the rest, are unfortunately not sufficiently interested in our existence as a learned body, devoting our best energies to the public good, to care much about us.

Passing over, therefore, briefly, the subject of medical education, as being but slightly connected with the first steps in medical reform, and as being a matter rather to be left to the profession itself, whether it shall experience these alterations, or whether it be destined to remain exactly in its present state, I may yet perhaps be pardoned for throwing out a few hints to those powers who now regulate, or in future may regulate, this important subject.

The best general education will always be found the best and surest foundation for a professional one. A good general education should, therefore, not only be encouraged, but even required, previously to entering upon professional studies. In conducting professional education, the great object to be attained should never be lost sight of. Now, as the great bulk of medical students are destined to be practitioners, their education should be eminently practical; it is therefore most desirable that, both in their education, and in their examinations, which are intended to test the effects of that education and their qualification to enter upon the duties of their profession, this point should never be lost sight of.

The importance of anatomical studies cannot be too strongly insisted upon, both in the education of the physician and the surgeon; for how can the physician otherwise read those symptoms of disease which are only explicable by the aid of anatomy and physiology, or how discern the slighter, or even coarser shades of disease in structures of whose healthy appearance even he is ignorant? and how can the surgeon direct his knife through a labyrinth of delicate structures, of whose relative position he knows nothing? Anatomical studies should therefore be commenced with in the first stage of medical education, and continued throughout its progress; the more so, in that opportunities are at this season offered to the student which but few will have the privilege of enjoying in after life.

In the universities, and other large schools of learning, it has long been observed that a series of minor examinations, at short intervals, greatly promote the acquirement and retention of knowledge, and it is with no small satisfaction that I have seen this hint adopted in some of our large hospitals. Such a plan might be advantageously insti-

tuted in the proceedings of our present or future boards of examiners for medical diplomas. A person is less likely to cram for a series of minor examinations than for one grand climacteric effort, with the overcoming of which the idler thinks his labours are to close. This plan might, with especial advantage, be applied to anatomical studies. Anatomy may be said to be learnt by the head and the eye; it does not require, therefore, great mental powers to acquire, but is difficult of retention. Now as anatomy is readily divisible into certain portions, it would be easy to examine the student the first year in one branch of anatomy, the second year in another branch, and finally in the whole subject.

One useful hint, which, if my memory serves me right, has been suggested by yourself, towards the rendering of the examination more practical, is, that the pupil to be examined might be left to investigate several cases, and then to put down on paper his diagnosis, prognosis, and the plan of treatment he would adopt.

I have now completed, as far as is in my power, a general outline of my views respecting medical reform; I shall, however, beg your indulgence for one more letter upon a few more general subjects connected with our profession; and in the meanwhile believe me to remain, sir,

Your obedient servant,
PHILOMATHES.

April 5, 1843.

THE PHYSICIANS OF DANTZIC SIXTY YEARS SINCE.

THE character of our Danzig physicians of that day left my father not the faintest hope of effecting his purpose by their means. In the first place, they were all and several extremely old, and petrified in obstinate prejudices. Whether they had ever been young, where they had lived, and what they had done in their youth, I know not; but I can affirm, that up to the twelfth or fourteenth year of my life, I had never seen nor heard of a young physician. These reverend gentlemen enjoyed the title of excellency, and not only in their own houses and from their own servants, but in society generally; only very intimate friends could sometimes venture on a respectful "Herr Doctor." Their head was covered by a snow-white, powdered, full-bottomed periwig, with three tails, one of which hung down the back, while the others floated on the shoulders. A scarlet coat embroidered with gold, very broad lace ruffles and frill, white or black silk stockings, knee and shoe buckles of

sparkling stones, or silver gilt, and a little, flat, three-cocked hat under the arm, completed the toilette of these excellencies. Add to this a pretty large cane, with a gold head, or mermaid carved in ivory, upon which, in difficult cases, to rest the chin—and certainly every one will admit the impossibility of so much as thinking of an innovation in their presence.—*Edinburgh Review*, Feb. 1843, from Mad. Schopenhauer's *Jugend-leben*.

[The innovation alluded to is inoculation of the small-pox.]

ANEURISM BY ANASTOMOSIS— LIGATURE—CURE.

A FEMALE child, *ætat.* three months, was brought to the hospital on the 14th February, with an aneurism by anastomosis of moderate size, seated a little in front of the anterior fontanelle. The mother stated that at birth it was but just visible, that its growth latterly had been rapid, and that it was daily increasing. Two needles were passed transversely beneath the base of the tumor, taking care that they should enter, and pass out a little distance beyond the diseased structure, after which a ligature was drawn around its base sufficiently tight to strangulate it. Two days afterwards the pins were removed, and a poultice of slippery elm applied to hasten the separation of the slough. This came away on the following day, leaving a healthy ulcerated surface, which in a short time was completely cicatrised.

The mode of procedure adopted in the above case of transfixing the tumor by means of needles passed beneath it, at right angles with each other, and securing a ligature tightly around its base, is that which I usually employ, and is well adapted for the removal of all tumors of this kind, of moderate size; the operation being safe and quickly performed, and the pain caused by it but of short duration. The double ligature passed through the base of the tumor, which is often employed, may be followed by some hæmorrhage after the tightening of it, from the separation of the surfaces through which the needle is passed; besides which, the shape or situation of the *nævus* may be such, as to make it very difficult to fasten the ligature on either side around its base, entirely beyond the limits of the affection. A single needle placed under the centre of the tumor is also generally insufficient to procure the enclosure of all the diseased part within the loop of the ligature.—*American Journal*.

PARALYSIS IN TEETHING CHILDREN.

WHILST on a visit to the parish of West Feliciana, La., in the fall of 1841, my at-

tention was called to a child about a year old, then slowly recovering from an attack of hemiplegia. The parents, (who were people of intelligence and unquestionable veracity,) told me that eight or ten other cases of either hemiplegia or paraplegia, had

occurred during the preceding three or four months within a few miles of their residence, all of which had either completely recovered, or were decidedly improving. The little sufferers were invariably under two years of age, and the cause seemed to be the same in all—namely, *teething*.—Mr. G. Colmer, in *American Journal*.

MEDICAL REFORM.

NORTH OF ENGLAND MEDICAL ASSOCIATION.

At a meeting of the Council of this Association, held at Newcastle-on-Tyne, Wednesday, April 12, 1843 (Dr. Headlam, president, in the chair), it was resolved unanimously, on the motion of Dr. Brown, of Sunderland, seconded by Dr. Charlton, of Newcastle:—

“That the cordial thanks of this meeting be given to Sir James Clark, Bart. for the able manner in which he has advocated the welfare and improvement of the medical profession, in the letters recently addressed by him to the Right Honourable the Secretary of State for the Home Department.”

Resolved, on the motion of Dr. Knott, of Newcastle, seconded by T. M. Greenhow, Esq.:—

“That the foregoing resolution be forwarded to the Editors of the *Lancet*, *Medical Gazette*, and *Provincial Medical Journal*, with a request they will cause it to be inserted in their respective periodicals.”

DR. RICHARD BUDD.

This gentleman, a brother of Dr. Budd, of King's College, has just been elected Physician to the North Devon Infirmary, in the room of Dr. Britton, resigned.

LUMLEIAN LECTURES

DELIVERED AT THE
COLLEGE OF PHYSICIANS,

MARCH 1843,

BY GEORGE BURROWS, M.D.

Physician to St. Bartholomew's Hospital.

LECTURE I.

Introduction. Modifications which the circulation within the cranium is capable of undergoing in health and disease. Opinions of Abercrombie, Kellie, Clutterbuck, Watson, and others, on the peculiarities of the circulation within the cranium. Quantity of blood within the cranium said to be nearly invariable. Experiments of Dr. Kellie to show that hæmorrhage does not deplete the vessels of the brain. Repetition of the experiments; whence it appears that anæmia of the brain is induced by fatal hæmorrhage. Experiments to show the striking effects of posture and gravitation on the quantity of blood within the cranium. Pathological and practical inferences from the foregoing experiments. Observations and experiments to determine the amount of congestion of the brain, when death takes place by Apnœa. Absence of cerebral congestion in some cases of death by suspension. Explanation of the anomaly.

IN addressing you, Sir, and the members of the College, on the present occasion, I think it is due to you and myself to premise, that, when the president, last autumn, did me the honour to select me as the Lumleian lecturer, I accepted the office with considerable reluctance, from the apprehension that my public duties during the winter months would unavoidably prevent the preparation of any thing worthy of being delivered from this chair, and before such an audience. It

is a bold attempt, and one of no ordinary difficulty, to satisfy the expectations of the learned, who have assembled here to listen to a dissertation on a subject with which they are already familiar; perhaps more so, than he who addresses them, *ex cathedra*.

We learn from the first oration of Demosthenes against Philip of Macedon, how much difficulty that great orator experienced in commanding the attention of his gifted countrymen, when their vital interests were at stake; and he thus describes the Athenians of his time—"περιϊόντες αὐτοῦ, πυνθάνεσθαι, κατὰ τὴν ἀγορὰν, λέγεται τι καινόν;" no doubt most of you have hesitated before you would sacrifice this hour, and have as you passed "κατὰ τὴν ἀγορὰν," enquired λέγεται τι καινόν; will he tell us any thing new? That it was only with such temptation of novelties that Athenians willingly spent their time, we learn from a higher authority. When St. Paul visited Greece, he found the Athenians so superior in intellectual acquirements to all their contemporaries, "εἰς οὐδὲν ἕτερον εὐκαίρουν, ἢ λέγειν τι καὶ ἀκούειν καινότερον." Well do I understand that you do not willingly give your attendance here, unless it be to hear (τι καινότερον) "something rather novel." How shall I attempt to satisfy your expectations in this respect? I will at least endeavour to perform the duties of a pioneer, and remove some errors which have long tended to obstruct our advances in the pathology of a most important organ—the brain.

The pathology of the brain and spinal cord has, indeed, of late years derived great and valuable elucidation from the improved physiology of these nervous centres. The functions of particular parts of the cerebro-spinal system have been clearly pointed out by a succession of experimentalists following in the path which was first so successfully trodden by our distinguished countryman, the late Sir Charles Bell. But the simplification of the pathology of many complex affections of these organs, which, although

bearing considerable resemblance in their symptoms, are in essence very different, "*facies non omnibus una, nec diversatamen:*" this has I believe been effected principally by Dr. Marshall Hall. While great progress has been made in the diagnosis of nervous affections, particularly in reference to the real source of irritation to the nervous centres, it appears to me that there has not been a corresponding advance in our pathology of affections of the brain depending on the state of the circulation in that organ.

I therefore propose, in this and the succeeding lectures, to inquire, first; what modifications the circulation in the brain is capable of undergoing in health and disease: secondly; how far the central organ of the circulation, the heart, when its circulating powers are increased or diminished, is capable of disturbing the functions of the brain, and in what manner these changes in the circulation affect the brain: and thirdly; I shall call your attention to a class of diseases of the heart, which are often overlooked, and which create great disturbance in the functions of the brain, or rather of the cerebro-spinal system.

Many physicians of high philosophical attainments have directed their attention to the peculiarities of the circulation within the cranium; and they, from experiments, and reasonings founded on the mechanical construction of the cranium, have arrived at the conclusion, that the absolute quantity of blood within the cranium is at all times nearly the same.

Pathologists, in apparent opposition to this conclusion, are in the habit of describing congestions of the blood-vessels of the brain, states of hyperæmia of that organ, and so on; while practical men are continually speaking of determination of blood to the heart, of plethora of the cerebral vessels; and assuming that such states actually exist, they employ various remedies to diminish these supposed conditions of repletion.

It will, I think, be not without interest and instruction, if we more closely investigate on what grounds the brain has been supposed to be exempted from these variations in the quantity of blood in its vessels, which are generally admitted to be such frequent pathological conditions of the vascular system in other organs.

This doctrine of the invariable quantity of blood within the cranium, was first asserted, as far as I can ascertain, by the second *Monro*, at *Edinburgh*. His opinions on this subject are recorded in his work on the *Brain and Nervous System*. He observes,* "as the substance of the brain, like that of the other solids of our body, is nearly in-

compressible, the quantity of blood within the head must be the same at all times, whether in health or disease, in life or after death, those cases only excepted in which water or other matter is effused or secreted from the blood-vessels; for in these cases, a quantity of blood, equal in bulk to the effused matter, will be pressed out of the cranium."† Such was the opinion of *Monro*: others who have followed him have pushed this doctrine to a much greater extent.

Monro used to illustrate this doctrine by exhibiting a glass-ball filled with water, and desiring his pupils to remark that not a drop of the fluid escaped when its aperture was inverted.

In an appendix to Dr. *Abercrombie's* admirable work, entitled "*Pathological and Practical Researches on the Brain and Spinal Cord*," he has given, under the modest title of "*Conjectures in regard to the Circulation in the Brain*," some most interesting and original views on this point of physiology. Dr. *Abercrombie* informs his readers that his views are primarily founded on the appearances of the brain in animals which have been bled to death. "While in such animals all the other organs have been completely drained of blood, the brain has in general presented, in this respect, its usual appearance, and in some cases the superficial cerebral veins have even been found distended."

On the other hand, when similar experiments were repeated on other animals after a small opening had been made in the cranium by the trephine, the brain was found as much drained of blood as any other part of the body. Dr. *Abercrombie* quotes as his authority for these remarkable conditions of the brain, the experiments of Dr. *Kellie*, detailed in Vol. I. of the *Transactions of the Medico-Chirurgical Society of Edinburgh*.

These unexpected phenomena may, according to Dr. *Abercrombie*, be explained by reference to the peculiarities in the structure of the head. "The cranium," he observes†, "is a complete sphere of bone, which is exactly filled by its contents, the brain, and by which the brain is closely shut up from atmospheric pressure, and from all influence from without, except what is communicated through the blood-vessels which enter it. In an organ so situated it is probable that the quantity of blood circulating in its vessels cannot be materially increased, except something give way to make room for the additional quantity, because the cavity is already completely full; and it is probable that the quantity cannot be ma-

* *Observations, &c. on Nervous System*. Alexander *Monro*, M.D. 1783.

* *Medico-Chirurgical Transactions of Edinburgh*, vol. i. p. 2.

† *Op. cit.* p. 302.

terially diminished except something entered to supply the space which would become vacant. Upon the whole, then, I think we may assume the position as being in the highest degree probable, that, in the ordinary state of the parts, no material change can take place in the absolute quantity of blood circulating in the vessels of the brain."

The accuracy of the experiments of Dr. Kellie, and his inferences from them, have not only been adopted by Dr. Abercrombie, and explained by arguments founded on the immutable laws of physics, but they have also been sanctioned by some of the first medical authorities of the present day.

Dr. Watson* entertains the opinion that the brain is the only organ which, under the ordinary state of the parts, contains at all times the same quantity, or very nearly the same quantity, of blood. "This depends," remarks Dr. Watson, "upon the mechanical construction of the cranium, and is capable of explanation upon the known principles of hydraulics." "This conclusion, which would be arrived at by *à priori* reasoning, is confirmed by certain very curious experiments performed by Dr. Kellie, of Leith, from which we learn that, in animals bled to death, the brain presented its ordinary appearance, or even seemed to contain more blood in its superficial vessels than usual; and in one instance the sinuses were loaded with dark blood, and the pia mater injected with florid blood."

Other modern writers on the pathology of the brain have carried these theories of Dr. Kellie and Dr. Abercrombie still further. Thus we find it stated by Dr. Clutterbuck, in his article on Cerebral Apoplexy, in the *Cyclopædia of Practical Medicine*, "that no additional quantity of blood can be admitted into the vessels situated in the brain, the cavity of the skull being already completely filled by its contents. A plethoric state, or over-fulness of the cerebral vessels altogether, though often talked of, can have no real existence; nor, on the other hand, can the quantity of blood within the vessels of the brain be diminished. No abstraction of blood, therefore, whether it be from the arm or other part of the general system, or from the jugular veins (and still less from the temporal arteries), can have any effect on the blood-vessels of the brain, so as to lessen the absolute quantity of blood contained within them."

Thus Dr. Clutterbuck not merely adopts the opinion of Dr. Abercrombie, that in the ordinary state of the parts no material change can take place in the quantity of blood in the vessels of the brain, but he maintains that no abstraction of blood can lessen the quantity of blood in them.

Dr. Kellie's experiments (as quoted by

Dr. Abercrombie) are cited by Dr. Clutterbuck in support of his opinions.

Such, then, are the physiological doctrines with respect to the peculiarities of the circulation in the cranium, which have been promulgated by many distinguished writers and teachers of the present day.

One and all appear to refer to the experiments of Dr. Kellie, and to the mechanical structure of the cranium, in support of this theory of the invariable quantity of blood in the vessels of the cranium. Permit me, then, now to draw your attention to the experiments and conclusions of Dr. Kellie, as they stand recorded in the *Transactions of the Medico-Chirurgical Society of Edinburgh*, Vol. I. I am more strongly induced to give an abstract of these experiments, because I suspect that most writers on this subject, subsequent to the publication of Dr. Abercrombie's work, have been satisfied with his allusions to the experiments of Dr. Kellie, and that few have taken the trouble to analyse the original account of them in the work just alluded to. As I proceed with this abstract, I shall detail analogous experiments performed by myself. The physiological conclusions deduced from them will contrast very forcibly with the opinions on this peculiarity of the cerebral circulation which have been maintained by Dr. Abercrombie, Dr. Kellie, and other modern British authors.

Dr. Kellie performed a series of experiments, from which he inferred—

1. That a state of bloodlessness is not discovered in the brains of animals which have died by hæmorrhage; but, on the contrary, very commonly a state of venous cerebral congestion.

2. That the quantity of blood in the cerebral vessels is not affected by gravitation, or posture of the head.

3. That congestion of the cerebral vessels is not found in those instances where it might be most expected; as in persons who die by hanging, strangulation, suffocation, &c.

4. That if there be repletion or depletion of one set of vessels (arteries or veins) in the cranium, there will be an opposite condition of the other set of vessels.

I shall proceed, first, to detail a few of the experiments performed by Dr. Kellie, and from which he has concluded that, when death takes place by hæmorrhage, it has not the effect of depleting the cerebral vessels; but, on the contrary, that in such cases the cerebral veins contain as much, or even more, blood than is usual.

Dr. Kellie's experiments are enumerated by letters. We will take the experiment E.

"In this experiment both carotids of a sheep were tied, and four minutes after the jugular veins opened. The quantity of blood lost was 3xxxviiij., when the animal

* Lectures on Medicine, *MED. GAZ.* Vol. 27.

died. The heart contained no appreciable quantity of blood. The sinuses of the brain were in their usual state; those at the basis contained less blood than had been found in similar experiments, and the veins on the hemispheres were less filled; the choroid plexus was pale and empty: the vessels on the basis of the cerebrum were better filled, and those on the basis cerebelli minutely injected."

Exp. II.—"A dog was bled to death from the carotids, having lost 3xxxvij. of blood. The viscera in general were well drained of their blood. The dura mater contained little blood: the lateral sinuses were, however, well filled. On the pia mater were several vessels of a florid colour, but not turgid. This brain seemed upon the whole more depleted than usual."

Now contrast the appearances of the vascular system of the brain in the two foregoing experiments, where the animals died by hæmorrhage, with the condition of the brain in two other animals, where death was caused by other means.

Exp. L.—Both carotids and both jugulars were tied in a dog, an operation which it survived twelve hours. The vessels of the dura mater were remarkably turgid, and all the sinuses much loaded with blood. Both the larger and the smaller vessels of the pia mater were fully injected with red blood. Not only the pia mater through its whole extent, but the cineritious substance, had a suffused, reddened, and, as it were, blood-shot appearance. "In short," writes Dr. K., "this brain was gorged with blood in all its minuter vessels," and was obviously in a very different state of vascularity to those of animals bled to death in the experiments E and H.

Let us analyse another experiment (M). In this a dog was poisoned with prussic acid. "The sinuses and veins were found loaded and congested, and the brain was every where turgid with blood. It was quite evident (writes Dr. Kellie) that this brain, and that of the dog (L), contained, beyond all doubt or dispute, a much larger quantity of red blood than the brains of any of the animals which had been bled to death. These comparative experiments afforded us the most satisfactory proof that the other brains had been really depleted by bleeding, and their vessels drained of a very sensible proportion of the red blood usually contained by them." (Page 115, *op. cit.*)

The summary of these observations is thus stated: that though we cannot entirely or nearly empty the vessels of the brain, as we can the vessels of the other parts of the body, it is yet possible, by profuse hæmorrhage, to drain it of a sensible portion of its red blood. If, instead of bleeding *usque ad mortem*, we were to bleed animals more

sparingly but repeatedly, there is no doubt that we should succeed in draining the brain of a much larger quantity of red blood, although serous effusion would be increased.

It may, then, appear surprising that Dr. Kellie has been so often quoted as asserting the brain cannot be depleted by blood-letting, when we find him stating, his experiments satisfactorily proved that these brains had really been depleted by bleeding, and their vessels drained of a very sensible proportion of the blood usually contained in them. But in opposition to the conclusions drawn from these experiments, we find, in a subsequent communication to the Medico-Chirurgical Society of Edinburgh, Dr. Kellie affirming "that, in the ordinary state of the parts, we cannot lessen, to any considerable extent, the quantity of blood within the cranium by arteriotomy or venesection;" whereas, if the skull of an animal be trephined, then hæmorrhage will leave very little blood in the brain.

This apparent contradiction between the results of experiments and subsequent statements induced me to repeat the experiment of bleeding animals to death, and comparing the state of the cerebral blood-vessels in them and in animals which had died from other causes.

In justice to myself I wish to state that, if I could have found any series of experiments, performed by others, which corroborated or invalidated the opinions of Dr. Abercrombie and Kellie, I should have refrained from the needless repetition of similar experiments on living animals. I have, however, up to the present time, fruitlessly searched for any additional information on this interesting point in physiology, a point which has such direct bearings on practical medicine. I had anticipated finding in Dr. Marshall Hall's work "On the Effects of Loss of Blood," the desired information; but it does not appear that, at the time of the publication of that volume, the author had made any examination into the state of the blood-vessels of the brain after hæmorrhage; for he remarks "that we are altogether in want of a series of observations on the effects of loss of blood on the internal organs." Thus disappointed in my search for information on this subject, I determined to resort to fresh experiments.

On the 11th of January, 1843, I killed two well-grown rabbits. The one (A) by opening the jugular vein and carotid artery on one side of the throat; the other (B) was strangled. Each animal died violently convulsed. A ligature was drawn tightly round the throat of the rabbit (A) immediately it expired, to prevent any further escape of blood from the vessels of the head. The rabbits were allowed to remain twenty-four hours on a table resting on their sides.

While the blood was flowing from the rabbit (A), the conjunctiva was observed to become pallid, and the eyeballs to shrink within the sockets. Upon the examination of the head of this rabbit, the integuments and muscles appeared blanched and exsanguined. Upon removing the upper portions of the cranium, the membranes of the brain were found pallid, and scarcely the trace of a blood-vessel was to be detected on the surface of the brain. The longitudinal and lateral sinuses were nearly empty of blood, and their course was not denoted by any colour of blood. Upon making sections of the brain, the interior appeared equally exsanguined.

Soon after the cord was drawn tight round the throat of the rabbit (B), the conjunctiva became congested, the eye-balls turgid, prominent, and even projecting beyond the margin of their sockets. The integuments and muscles of the head were found full of blood. Upon opening the cranium, the superficial vessels of the membranes, as well as the sinuses, were full of dark liquid blood. The whole substance of this brain, and its membranes, appeared of a dark reddish hue, as if stained by extravasated blood.

The contrast between the two brains in point of vascularity, both on the surface and the interior, was most striking*. In the one scarcely the trace of a blood-vessel was to be seen; in the other every vessel was turgid with blood. It seems hardly necessary to bring forward further evidence to prove that death by hæmorrhage has a most decided effect in depleting the vessels, and reducing the quantity of blood within as well as upon the outside of the cranium.

I have, however, repeated the experiments with similar results†. In fairness to Dr. Kellie I should state, that I have attended at the slaughtering of sheep by butchers, and find the brains of those animals much less depleted than the brains of rabbits which have died by hæmorrhage. But these sheep did not die from simple loss of blood; but partly from division of the pneumogastric nerves, and cervical portion of the spinal cord. These lesions, no doubt, influenced the appearances.

Hence it is not a fallacy, as some suppose, that bleeding diminishes the actual quantity of blood in the cerebral vessels. By abstraction of blood we not only diminish the momentum of blood in the cerebral arteries, and the quantity supplied to the brain in a given time, but we actually diminish the quantity of blood in those vessels. Whether the vacated space is replaced by serum, or

resiliency of the cerebral substance under diminished pressure, is another question, into which I do not now enter.

2dly.—Dr. Kellie, assuming the cranium to be a perfect sphere, proceeds to show that the quantity of blood in the cerebral vessels is not affected by posture.

“I think,” writes Dr. K. “it quite certain, at least in a previously sound and healthy condition of the brain and its vessels, no change of posture can impel into, or confine more or less blood within, those vessels than naturally belongs to them; though I am willing to allow that the general pressure of the circulating fluid may in this way be, under certain circumstances, increased or diminished, and the circulation through the head accelerated, retarded, or disturbed.”

In order to ascertain, as far as such an experiment can do, the total effect of the gravitation of the blood upon the vessels of the brain, Dr. K., immediately after administering a destructive dose of prussic acid to two dogs, suspended the one by the heels, and the other by the ears. He allowed them to remain thus suspended for 18 hours, when they were taken down for examination.

The effects of posture on the parts exterior to the skull Dr. K. reports to be very great. In the former animal the integuments and their vessels were filled and congested to the greatest possible degree; the integuments of the head of the second dog were pale, and the vessels empty. “Within the head,” continues Dr. K., “the contrast was but trifling. The sinuses beyond all doubt were loaded in the first case, and rather empty in the other; the difference of appearance in other parts of the brain was but little striking.” Dr. Kellie’s own words, as to the condition of the sinuses in the two animals, assured me that posture had a much greater effect on vascular congestion of the brain than he was willing to admit. I therefore repeated his experiment.

On the 28th of December, 1842, two full-grown rabbits were killed by prussic acid, and, while their hearts were still pulsating, the one (C) was suspended by the ears, the other (D) by the hind legs. They were left suspended for 24 hours; and, before they were taken down for examination, a tight ligature was placed round the throat of each rabbit, to prevent, as effectually as was possible, any further flow of blood to or from the head, after they were removed from their respective positions.

In the rabbit (C) the whole of the external parts of the head, the ears, the eye-balls, &c. were pallid and flaccid; the muscles of the scalp and bones of the cranium were also remarkably exsanguined. Upon opening the cranium, the membranes and substance of the brain were pallid, the sinuses and other vessels were exsanguined; anæmic beyond my expectation.

* Coloured drawings of the brains of these animals were exhibited.

† The craniums of these rabbits opened were exhibited for inspection.

In the rabbit (D) the external parts of the head, the ears, eye-balls, &c. were turgid, livid, and congested. The muscles and bones of the cranium were of a dark hue, and gorged with blood, which at some parts appeared extravasated. Upon opening the cranium, the membranes and vessels were dark and turgid with liquid blood; the superficial veins were prominent, the longitudinal and lateral sinuses were gorged with dark blood, and there was staining of the tissues, if not extravasation of blood into the membranes. The substance of the brain was uniformly dark, and congested to a remarkable extent.

Dr. Kellie asserts, but I think his experiments do not support him, that the contrast in the appearances within the heads of the two animals was but trifling. In my analogous experiments the contrast was most striking. In the one was to be seen a most complete state of anæmia of the internal as well as external parts of the cranium; in the other a most intense hyperæmia or congestion of the same parts; and these opposite conditions in the vascularity of the brain induced solely by posture, and the consequent gravitation of the blood*.

If the cranium were the perfect sphere, as taught by Monro, and as subsequently maintained by Abercrombie and other distinguished writers on the pathology of the brain, these effects on its circulation (which I have now exhibited) ought not to have resulted from the force of gravity on the blood in the cerebral vessels.

From the foregoing experiments it would appear, that the principle of the subsidence of fluids after death operates on the parts contained within the cranium, as well as upon those situated in the thorax or abdomen.

It is well known that, in former times, the stains, or *sugillations* as they are technically termed, which are discovered on the integuments of the under parts of a corpse, were not unfrequently mistaken for the effects of violence done to the body during life. Within a more recent period the cadaveric congestions of the posterior part of the lungs and of depending convolutions of the intestines have been mistaken for the effects of inflammation. M. Orfila and M. Trousseau have done much to dissipate those pathological errors. In the article "Pseudomorbidity appearances," Cyclopædia of Practical Medicine, I find Dr. Todd gives a caution, that, in estimating the colour of the cerebral substance, allowance must be

made for the quantity of fluid blood in that viscus, as well as for the position in which the head of the corpse has been laid since death. I hence infer that this able anatomist coincides in the opinion that the quantity of blood in the brain varies during life, and is affected by posture after death. It may now be inferred that the encephalon is not exempt from this law in physics—the gravitation of the fluids to the lowest parts of the corpse.

The discovery of the operation of this force on the blood within the cranium after death, suggests a precaution very essential to be followed, when it is desired to ascertain the precise amount of congestion of the cerebral vessels at the time of death. In such cases a ligature should be placed around the throat of the corpse, and drawn sufficiently tight to compress the cervical vessels, and arrest all flow of blood through them. This precaution will be most required in the examination of bodies, where, from the kind of death, the blood may be suspected to remain fluid in the heart and great blood-vessels. The depending or elevated position of the head during the examination of the body will not then induce deceptive appearances, which mislead us in our conclusions as to the previous amount of congestion in the cerebral vessels.

The third argument against the occasional repletion of the vessels within the cranium is founded on the reported condition of these vessels in those kinds of death where cerebral congestion might have been fairly anticipated, as in death by hanging, suffocation, drowning, and so on; or in death by asphyxia, as it was formerly termed, but more correctly by apnœa. In support of this position, that cerebral congestion is not discovered when death takes place by asphyxia or apnœa, Dr. Kellie adduces an account of the appearances in the bodies of two pirates, who were hung at Leith, and dissected by Monro and himself. The bodies were examined while yet warm; the limbs were not rigid; the countenances livid, and the eyeballs suffused. In each body, on the division of the scalp, blood flowed from its vessels in such quantity as to afford ample proof of congestion of the external parts of the head. The sinuses of the dura mater contained no extraordinary quantity of blood; the large vessels on the surface of the brain were but moderately filled; the pia mater was paler and less vascular than it is found in ordinary cases. No sooner was the brain removed from the skull, than the blood, yet warm, began to rise, and flow profusely from the divided sinuses and vessels at the base of the skull: about one pint of fluid blood thus escaped, and conglobated on the floor.

That the brain and its membranes are not necessarily congested in the bodies of those

* Coloured drawings of the brains of these animals were exhibited, as well as the craniums of two other animals killed in the same way, and then laid open for comparison. The effects of posture on the quantity of blood in the cerebral vessels were also exhibited by drawings made from the brains of animals killed by placing a ligature around the trachea, and then suspending the one animal by the ears, but leaving the other resting on its side.

who have died by hanging, is corroborated by the detail of the condition of these parts in the body of Bishop, the resurrection-man, who was hung for the murder of Carlo Ferrer, in Nov. 1832. Dr. Watson states*, that the integuments of the head and face were turgid with blood; the inner surface of the scalp and outer surface of the skull red and bloody; very dark-coloured blood ran from the divided integuments; but when the bones of the head were sawn through, and the skull-cap removed, the large veins of the brain did not appear unnaturally full.

One more instance, equally worthy of credit, may be cited in proof of this condition of the vessels of the brain of those who have died by hanging. M. Esquirol gives the following account of these parts in the body of a woman who hung herself, and was found suspended six hours after death. The face was livid and bloated; the scalp was loaded with fluid blood, while the membranes of the brain were slightly vascular, and the brain itself natural.

The appearances in the brains of these persons who died by hanging would appear to support the opinion that the cerebral vessels are not congested or overloaded in those cases where such a condition might be fairly expected. But, in opposition to such a conclusion, it would not be difficult to cite numerous well-authenticated instances of death by hanging, where the brain and its membranes have presented all the usual appearances of congestion, and even of apoplexy, to a striking extent. In the late Dr. Cooke's learned work on Nervous Diseases (which was the substance of his Croonian Lectures, delivered at the College in 1819), there will be found some remarkable examples of this kind. Sir B. C. Brodie informed Dr. Cooke, that he found congestion and extravasation of blood to a large amount in the brain of a man who had been hanged. The late Dr. Hooper had in his collection the brain of a person who died by hanging, and which exhibited the effusion of a great deal of blood into the membranes. M. Portal reports that, upon the examination of the bodies of persons who had been hanged, and which were brought to him for anatomical purposes, at Paris, a large quantity of blood was found in the vessels of the brain, or extravasated into that viscus.

But I would fain relate the pathological appearances in one other case of death by suspension; because, from the rank of the individual, and the peculiar circumstances under which he died, the examination of the body was made with the most scrupulous attention by several scientific men, well qualified for their task.

In the autumn of 1830, a few months

after the French Revolution, the Duke de Bourbon, the last of the Condés, was found dead in his bed-chamber, suspended by a couple of cravats to the fastening of his window shutter. His toes were slightly resting on the floor, which posture of the body, together with the advanced age of the Prince, his known infirmities, and certain political reasons, led to the suspicion that he had been murdered, and afterwards suspended, to give the appearance of suicide. His body was carefully examined by MM. Marc, Marjolin, Pasquier, and others. They reported* that the vessels on the surface of the brain, especially on the anterior lobes, were gorged with dark *fluid* blood. Three ounces of serum were found in the ventricles and membranes of the brain. The lungs were also gorged with black *fluid* blood. The cavities of the heart devoid of blood. It was their opinion that the Duke had destroyed himself by hanging, and that death was induced by the *accumulation* and stagnation of blood in the brain and lungs.

But let it not be supposed that I have adduced these examples of cerebral congestion and cerebral hæmorrhage, in individuals who have died by hanging, in support of the theory that in this kind of death life is destroyed by apoplexy. It is well ascertained that obstruction to respiration is the principal cause of death in such cases. I have adduced these examples of intense cerebral congestion, where death was caused by hanging, to contrast with those other instances which have been cited as proofs that cerebral congestion is not found after this mode of death.

That an intense congestion of the cerebral vessels is discovered after death produced by various kinds of obstruction to respiration, is manifest from the experiments and drawings which I now offer to your notice by way of illustration†. But how are we to account for the undoubted occasional absence of this congestion of the cerebral vessels in those who have died by hanging?

When criminals are hung by the executioner, the knot of the rope is usually adjusted on one side of the neck; and it is found, after death, beneath the ear, resting on the mastoid process. It has been often observed, in the dissection of such criminals, that the cheek and integuments on this same side of the head are not near so livid and congested as on the other side. The pressure of the rope has not completely obstructed the return of blood through the external jugular vein on the one side, although it has effectually stopped the current on the other. In such cases it is probable

* Annals d'Hygiène, Vol. 5.

† Drawings to illustrate—Death by strangulation; death by ligature on the trachea; death by drowning.

that the deep-seated internal jugular vein on the one side has only been partially compressed, and has permitted to a certain extent the return of blood from the internal parts of the cranium.

But there is another still more efficient cause of this occasional absence of congestion of the cerebral vessels after death by hanging; it is the subsidence of the *fluid* blood after death, while the body is yet suspended, through the cervical vessels which are not completely obliterated by the pressure of the cord. And it should be recollected, there are some channels which are scarcely if at all affected by the compression of the rope. These other channels are the vertebral sinuses, and spinal plexus of veins, so ably delineated by M. Breschet. Well may we adopt the language of Haller, in describing this complex contrivance to carry off the blood from the nervous centres:—
"Magna pulchritudo est sinuum, qui duræ matri medullæ spinalis adcumbunt, venæque potius sunt, quam sinus," writes Haller; and after describing the circular distribution of these vessels, and their free communication with the cervical, intercostal, lumbar, and sacral veins, he says, *"Eorum annulorum supremus cranioque proximus, cum sinibus occipitalibus et cum fossis jugularibus unitur."* From this description we learn that the sinuses of the cranium may be drained through these vertebral sinuses. (Illustrated by diagram.)

Having already directed attention to what extent gravitation alone can deplete the cerebral vessels after the heart has ceased to beat, it cannot now be a matter of surprise that, in some of those who die by hanging, and whose bodies remain suspended for a considerable length of time after death, the fluid blood should gravitate, and that the "large veins should not appear unnaturally full," or even less distended than in some ordinary cases.

But the true state of the cerebral vessels in the bodies of those who have died by hanging, is often incorrectly estimated, from the anxiety to examine the lesions produced by the compression of the rope on the larynx and trachea, as well as the condition of the heart and lungs. In making such examinations all the great vessels of the neck are usually cut across, and the thoracic organs removed from the body before the head is examined. While the head is elevated during the operation of removing the skull-cap and examining the brain, the *fluid* blood gravitates from the cranium, and pours from the divided cervical vessels into the chest; and then, to the surprise of the by-standers, "the sinuses of the dura-mater, and the larger veins on the surface, are found but moderately filled," or "do not appear unnaturally full."

That these are the causes tending to diminish the congestion of the cerebral vessels, when death takes place by hanging, appears to me probable from the intense congestion of the same vessels discovered in other examples of apnoea, where life is annihilated by obstruction to respiration, and where gravitation has had no effect upon the blood in the cranium.

These appearances are exhibited in the drawings made from the brains of animals that died by strangulation and suffocation, and which are exposed for inspection.

The deductions from the foregoing experiments are supported by the authority of one of the best and most recent writers on asphyxia. Dr. Carpenter states,* that when death is produced by the forcible compression of a ligature round the neck, to such an extent as to impede or prevent respiration, the veins and sinuses of the head partake of the general venous congestion; and in well-marked cases an unusual number of red points are seen on slicing the brain. An apoplectic extravasation is sometimes, though rarely, found in simple asphyxia, but is more frequent in death by hanging or strangulation.

"It can scarcely be doubted," writes Dr. Carpenter, "that these variations in the congestion of the brain depend principally on the mode in which the ligature is applied to the neck:" and from a series of experiments detailed in the *Annales d'Hygiène*, Vol. 8, it would appear that the apoplectic condition of the brain is less likely to be found in proportion to the proximity of the ligature to the lower jaw, which is its exact situation in death by hanging. Enough has been said on this point of the pathology of the brain, to prove that, in the majority of instances, when death takes place by strangling, hanging, suffocation, drowning, and so on, that a congestion of the cerebral vessels is found after death. The same condition of the brain is also found after death from those diseases which obstruct the return of venous blood from the brain. And where such congested state of the cerebral vessels is not marked in cases of death by apnoea, the absence of congestion may often be accounted for from the subsidence of the blood, which is facilitated by its fluidity, and the posture of the body after death.

I must now postpone the further consideration of this subject until the next opportunity of addressing you.

LECTURES
ON THE
PHYSICAL AND PATHOLOGICAL
CHARACTERS OF URINARY
DEPOSITS,

Delivered at Guy's Hospital, London,

BY DR. GOLDING BIRD.

LECTURE VI.

Pathology of deposits of triple phosphate and phosphate of lime—fætid urine—phosphates in old people—in irritable bladder—treatment—siliceous deposits—organized deposits—blood-discs; supposed filament in—pus—mucus—organic globules—ferment—torula cerevisia—epithelial debris—analytic table.

IN my last lecture I described to you the general properties and chemical characters of the different forms of deposits in which phosphoric acid enters as a constituent*. I also, you will recollect, pointed out to you the probable origin of the phosphoric acid existing in these saline combinations, and demonstrated to you, from the most trustworthy analyses to which I could refer, the fact that more phosphoric acid was taken into the stomach with the food than was excreted in the urine. I have now to direct your attention to a brief view of the pathological conditions under which such deposits most generally occur.

One general law certainly appears to govern the pathological development of the phosphatic deposits; I allude to a constantly depressed state of nervous energy, often general, rarely more local, in its seat. Of the former, the result of wear and tear of body and mind in old people, and of the latter the effects of local injury to the spine, will serve as examples. It is true that, in the majority of cases in which phosphates are deposited, there may be much irritability present; you may find an irritable pulse, a tongue white on the surface and red at the tip and edges, with a dry, and perhaps occasionally hot, skin. Still, it is irritability with depression—a kind of erythism of the ner-

vous system, if I may venture to use such a term.

Triple phosphates (neutral).—Where the deposit consists of this salt you will generally succeed in tracing its connection to some cause which has rendered the system morbidly irritable, at the same time that its tone or strength has been depressed. The simplest example of this kind that has occurred under my notice is in the case of individuals who have periodical duties to perform requiring extreme mental tension and bodily exertion. It has occurred to me more than once to notice this state of things in clergymen, especially in those who, from the nature of their secular engagements, have been accustomed to lead sedentary lives during the week, and to perform full duty on Sundays. One of the best examples I ever met with of this kind occurred in the person of a well-known and deservedly popular clergyman, who, from his connection with a public school, scarcely used any exercise during the week, whilst on Sunday he performed duty three times in his church. This gentleman was a tall, thin person, of dark complexion, and almost phthisical aspect. He was the subject of nearly constant dyspepsia. The urine passed by him on Saturday evening, as well as on Sunday morning, although repeatedly examined, appeared to be healthy, although of rather high specific gravity, generally containing a deposit of urate of ammonia. Before his Sunday duties were completed, he generally became the subject of extreme fatigue, with a painful aching sensation across the loins, in addition to the flatulence and epigastric uneasiness under which he generally laboured. The urine passed before going to bed, after the severe exertions of the day, was almost constantly of a deep amber hue, of rather high specific gravity, and deposited the triple phosphate in abundance. The urine of Monday would contain less of this salt, which generally disappeared on the following day, and again re-appeared on the following Sunday evening. This state of things I observed for several weeks, and it ultimately disappeared by the patient relaxing from his duties, and travelling for a few weeks.

It is not an uncommon thing to find an iridescent film formed of a thin layer, or pellicle, of crystals of triple phosphate, floating on the surface of urine passed by persons labouring under some form of irritative dyspepsia. This often presents the same brilliant colours as a soap-bubble, or thin layer of oil on water. It is clearly the result of imperfect assimilation, and, in all probability, is to be regarded as an attempt at getting rid from the system of an excess of the earthy phosphates which had been absorbed from the ingesta. In this form I have never seen a decided gravel or deposit.

* In my last lecture an important error in the amount of phosphates said to exist in the potato has occurred; it is stated to contain 23.56 grains in the ounce, instead of 2.356. This arose from the decimal point being misplaced in the table given by Dr. Bence Jones, (49.1 instead of 4.91) from whose work (on Gravel, Calculus, and Gout, p. 78) I copied it. In the text, at p. 16, *three* ounces has been placed for *four*; the meal I cited as an illustration would contain 30 grains of earthy phosphates instead of 114.

Four ounces of beef	1.52
„ „ wheat	19.08
„ „ potatoes	9.42
	30.02

produced, and I am inclined to consider that it is rather to be regarded as an index, and a valuable one, of the state of the assimilative functions, than as holding out any fear of the ulterior deposit of calculous matter.

I have not unfrequently met with deposits of the triple phosphates in very old people, in whom the state of decrepitude depending on senility had either become extreme, or been aggravated by low living and a want of the ordinary comforts of life. In several cases of this kind occurring in octagenarian dependents on parochial relief, I have found the urine very pale, of low specific gravity, subacid or neutral, and extremely foetid. The fœtor, which was like that of stale fish, did not appear to depend upon the presence of free ammonia, but in all probability was a result of some slow decomposition of the organic constituents of the urine; a decay depending on the depressed vital energy of the bladder.

I have before alluded to the fact, that a deposition of the triple phosphate is often observed to occur in cases where a blow had been received on the lumbar region, or where some strain has been experienced in that region; a fact first observed by Dr. Prout. This effect of injury to the loins is frequently met with as a temporary result of even slight blows or strains, and disappearing in a few days. I once saw a copious deposition of triple phosphates occur in the urine of a young gentleman who exerted himself rather more than his strength could bear in a riding school. In fact, whatever chemical explanation may be given to the presence of an excess of phosphates in the urine, it is indisputable that in the very great majority of cases there is ample evidence of the existence of some cause producing, to say the least, a depressed but irritable state of the nervous energies in the neighbourhood of the injury. The symptoms observed in these cases are nearly all explicable on this state of the nervous system.

The most prominent symptoms observed in these cases are, great irritability of temper, extreme restlessness, mal-performance of the digestive functions, with such imperfect assimilation of the ingesta, that a certain and often extreme amount of emaciation is a constant attendant. The appetite is uncertain, occasionally being voracious. Fatigue is induced by the slightest exertion; there is a remarkable inaptitude to any mental or bodily exercise, and the patient is often, from the exhaustion thus produced, unfitted for his ordinary duties. In acute cases these symptoms become aggravated by an excessive elimination of urea, which aids considerably in depressing the patient's strength.

Regarding the treatment of these cases, whilst we must allow that in many cases the administration of acids will cause the deposit of phosphates to disappear, yet it must be

admitted that we are thus treating but a symptom, although an important one, of a serious malady. It is, perhaps, wise to administer acids, especially the hydrochloric or phosphoric, and thus endeavour to render the urine sufficiently acid to prevent the crystals of the phosphate concreting into a calculus; but, at the same time, we must direct our treatment to the digestive organs, and endeavour to allay the morbidly irritable state of the nervous system. You will often find that it is no easy matter to render the urine acid in this manner; I have, in several cases, administered the mineral acids regularly, and in as large a dose as the patient could bear, without increasing the action of the urine on litmus paper, whilst in others the urine has appeared to be readily affected. This capricious effect observed in the use of acids renders their administration much less to be depended upon than when alkalis are given in cases where too much acid is secreted in the urine. The best mode of treating these cases is to regulate the bowels by tonic aperients, and allay the morbid irritability present by the use of sedatives. For this purpose, the *Mist. Gentianæ Compos.* may be made the vehicle for the administration of dilute hydrochloric acid in doses of fifteen or twenty minims, with half a drachm of the tincture of henbane thrice a day. In protracted and severe cases, the use of opium in graduated doses has, in the hands of Dr. Prout, been of great service. In one very severe case which occurred to myself I thought I found much relief in the administration of iron in the form of the acetate thrice a day, with a sedative at night. The preparations of zinc and silver also hold out great probability of being of service, from their well-known power in allaying morbid irritability of the digestive organs, and perhaps of the organic system of nerves generally.

With regard to the *pathological* indications afforded by the deposits of phosphate of lime, they are analogous to those already pointed out to you as peculiar to the triple salt. Intimately related as these salts are chemically, their pathological indications might be expected to be analogous; and such, indeed, is the case, if we except the not unfrequent excessive secretion of phosphate of lime as the result of disease of the mucous surface of the bladder. It is not uncommon to find both phosphates mixed in a deposit, which is thus readily fusible in the blow-pipe flame, unless too great an excess of either ingredient be present. These mixed deposits are not unfrequent in gouty people, and in such cases I have seen deposits of crystalline and amorphous phosphates alternate in the urine passed in the evening, whilst the morning secretion was loaded with urate of ammonia. So far as I have had an opportunity of watching the progress

of cases where phosphate of lime is deposited (and they are by no means of frequent occurrence) I have generally fancied that they present more marked evidence of exhaustion, and of the previous existence of some drain on the nervous system, than where the triple salt alone existed.

Occasionally, some curious cases are met with, in which phosphate of lime has come away in the urine for a long period without apparently doing much mischief. A very remarkable instance of this kind occurred in this hospital some years ago among the out-patients, in the person of an old man under the care of Dr. Hughes. This patient had for many years passed almost milky urine, which by repose deposited such an enormous quantity of phosphate of lime, that he brought to me at one time upwards of an ounce of this calcareous salt. He had been under the treatment of half the hospital physicians and surgeons in London, during fourteen or fifteen years, but his urine remained unimproved. He afterwards came under my care, but I found all the remedial measures I adopted useless: at the same time, I may remark, this man's health appeared so good that there was scarcely an excuse for submitting him to any course of treatment beyond the apprehension of the possible formation of calculus.

I cannot quit this part of my subject without pressing upon your notice the value derived in many of these cases from injecting the bladder with a very dilute mineral acid. I am confident that an irritable condition of the bladder, highly favourable to the secretion of earthy phosphates and excess of mucus from its mucous membrane, has been in some cases kept up by retention of phosphates in that viscus. Certainly, I have now seen many cases where viscid ropy mucus, mixed with abundance of phosphates, both magnesian and calcareous, have been secreted, and where the distress of the patient has been extremely increased by intense irritability of bladder. And in these, all plans of treatment have been unavailing, until the bladder has been carefully washed out by means of warm water, and an injection, consisting of half a dram of dilute hydrochloric acid, with a dram of vinum opii in half a pint of warm barley-water, has been thrown in by means of a double catheter, in the manner described by Sir B. Brodie. I had a case under my care last year, in consultation with a most excellent and talented provincial physician, Dr. Baker, of Maldon, in which the irritability of bladder was so intense that there was almost constant desire to pass water, attended with horrible suffering. The urine often contained blood, and rapidly underwent decomposition; it presented a copious dense deposit of puriform mucus, mixed with an enormous quantity of triple phosphate in very large

crystals. The state of distress to which this lady was reduced by the disease rendered her life a complete burden. On examining the urine carefully, I could detect no true pus; it did not coagulate by heat, and much of the opacity presented by the mucus was owing to the presence of the triple phosphate. I suggested the use of a solvent injection analogous to the one just described. Great difficulty was experienced in the use of the catheter, in consequence of the excessive suffering it produced. Ultimately the injection was very effectually administered by Mr. May, of Maldon, and the effect was most remarkable; the irritability of bladder rapidly subsided, and by repeating the injection it was completely removed, and on being called into Essex to a case in the neighbourhood some time after, I had the pleasure of seeing this lady apparently well.

Although it is not now my duty to point out to you the treatment of calculous affections, I felt anxious to draw your attention to this class of cases, on account of their great importance, and of the little notice taken of them by most writers, being generally confounded with the cases included under the general category of *catarrhus vesicæ*, or of irritable bladder.

I have little to say regarding the last ingredient of deposits made up of inorganic ingredients, viz:—

Silica, or silicic acid.

This substance exists in infinitesimally small quantities in some of the animal fluids, and therefore may by possibility be met with as an urinary deposit. I have, however, never met with an unexceptionable instance of its occurrence. It has been found in a calculus by the late Dr. Yelloly, and some others have recorded instances of its occurrence. Lassaigne* found a calculus consisting of nearly pure silica in the urethra of a lamb, and Wurzer† gives the analysis of a calculus removed from an ox, in which silicic acid existed to the amount of 38 per cent. You must, however, be on your guard regarding silicic concretions, for as there is a popular notion that calculous matter is *bond fide* gravel, whenever an imposition is intended a siliceous pebble is usually chosen to deceive the medical attendant. I have met with repeated instances of this kind, in which common rolled pebbles of quartz have been placed in my hands with the assertion that they were actually passed from the bladder. This has usually occurred in hysterical girls, who have laboured under that most unintelligibly morbid desire of deceiving the doctor, by representing themselves as afflicted with some ailment of the genito-urinary organs. I have heard of in-

* Recueil de Médecine Veterinaire, p. 445.

† Gurlt's Pathologische Anatomie der Haus-Sangethiere, B. 1. 840.

stances in which such pebbles have actually been thrust into the urethra by a girl, and thus have really reached the bladder. In a case mentioned to me by Dr. Christison, a piece of chlorite slate was found forming part of the supposed calculus, at once attesting its true origin, notwithstanding the positive assertions of the young woman who was said to have passed it, to the contrary. You have, I dare say, all heard of the case which occurred many years ago in this hospital, in which the late Mr. Cline operated, and removed from the bladder a quantity of common coals which had been introduced by the patient.

As, however, silica has been found in calculi by such excellent observers as the late Dr. Yelloly and Dr. Venables, and as the ox and lamb, mentioned by Wurzer and Lassaigne, could hardly be supposed to have put the silica into their own bladders, we must admit its possible occurrence in calculi. Still, that it is extremely rare, all experience has proved, as indeed might be anticipated, from the chemical relations of this most refractory substance.

I have next to direct your attention to a brief notice of

Deposits consisting of organised products.

Most of these have been carefully studied and well understood, but concerning some very little is known, and that little is anything but satisfactory.

Blood-discs.—Whenever a deposit consists wholly, or chiefly, of blood-particles, the urine generally possesses a tint which at once leads us to suspect the presence of some of the elements of blood. This tint varies from a pale dingy hue to a reddish brown, or, if the urine has become alkaline, a deep greenish colour is not of unfrequent occurrence. You will recollect that in my first lecture I pointed out to you the most prominent characteristics which distinguish urine containing blood-discs in diffusion.

Perhaps the best mode of detecting blood-discs in urine is to agitate it violently, and place a drop on a piece of glass; cover it with a piece of thin glass or mica, and examine it with a microscope furnished with a good object glass of $\frac{1}{4}$ or $\frac{1}{8}$ inch focus. If the urine has not been passed too long, you will find the blood-discs scarcely changed, except that they generally have their margins more sharply defined, and the surface more concave than usual. This arises, in all probability, from the sac of the blood-disc becoming partly emptied by exosmosis, in the manner so clearly and satisfactorily pointed out by Dr. Rees*. The peculiar appearances described by Dr. Martin Barry as indicating the existence of a

band or filament in the blood-disc is generally most beautifully marked in particles obtained from bloody urine, especially if it has been gently warmed, so as to facilitate the deposition of the discs before submitting them to the microscope. I have placed a specimen of some thus procured from bloody urine, preserved in dilute alcohol, in the collection of microscopic specimens, to which I have before alluded. These present the appearance of a spiral filament contained in the sac of the blood-disc. I confess I consider this appearance as a mere illusion, depending on the emptying of the sac by exosmosis, and the membranes consequently becoming congested in circular folds, thus producing the appearance of a spiral thread; and I believe an analogous explanation applies to all the cases of the supposed existence of filaments in blood, described by Dr. Barry. If blood-discs have long existed in urine they often become partly disorganised, their margins becoming irregularly crenate, and their whole form more or less irregular. You will find, however, notwithstanding the various changes produced in blood-discs by the action of urine, that they are seldom sufficient to alter it so as to prevent their ready recognition by microscopic examination.

Pus.—Whenever urine contains pus, it is always more or less coagulable by heat, as the pus particle is never secreted without its concomitant drop of serum, or *liquor puris*, in which it floats. Hence (at least if this view is correct) albuminous urine necessarily occurs when pus exists. Pus in urine, retaining its normal acidity, forms a cream-like layer at the bottom of the vessel, so closely resembling the fluid contents of an abscess, that there can be no great difficulty in identifying it. Here, however, a serious source of fallacy, to which I have alluded in my last lecture, exists, founded on the remarkably puriform appearances presented by some deposits of phosphates. The solubility of the latter in nitric acid will at once remove any difficulty in the diagnosis, unless puriform mucus exists with the phosphate, in which case the microscope can alone remove the difficulty.

If pus has remained long in the urine before it is submitted to examination, it will undergo certain changes which materially interfere with its generally recognised physical characters. It will undergo a change analogous to that produced by digesting pus in solution of common salt, as hydrochlorate of ammonia, described by Dr. Babington*, becoming in fact a ropy tenacious magma, more like purulent mucus than pus. This change is greatly accelerated, and, indeed, often produced immediately, if the urine is ammoniacal. The albuminous character of

* Guy's Hospital Reports, October 1841, and April 1843.

* Guy's Hospital Reports, Oct. 1837.

the urine, and microscopic examination of the deposit, will even then generally remove all doubt as to its true character.

The true pus particle strongly refracts light, and, being roughly granular on its surface, often appears coloured, unless the achromatism of the object-glass is perfect, and the illumination well arranged. These particles vary in size; on an average, however, it may be stated that they nearly correspond to the blood-disc in diameter. If a drop of acetic acid be mixed with a purulent deposit, and carefully examined after covering it with a thin plate of glass or mica, the compound structure of the pus particle will become obvious. The particles will present the appearance of being broken up or disintegrated, leaving numerous extremely minute transparent bodies of a tolerably regular spherical form, and about one-fourth the size of the original particle. These bodies are probably arranged as symmetric nuclei in the original particle, for certainly at least two or three exist in each before the addition of the acid.

Mucus.—Whenever a preternatural quantity of mucus is poured out by the lining membrane of the bladder, it is voided with the urine, and forms a deposit in the latter by repose, which is generally sufficiently characteristic to allow of its being readily recognised. Mucus generally forms a semi-translucent, somewhat gelatinous deposit, which, when the urine is decanted, falls from the vessel in the form of a tenacious rope, often of considerable length, sometimes so tough as to be actually sectile. Urine of this kind generally passes with great readiness into decomposition, and becomes alkaline, the mucus acting as a ferment, determining a molecular change of the fluid in which it is immersed without itself undergoing any manifest alteration. Urine containing any marked excess of mucus is generally alkaline, but if very recently voided is sometimes neutral and very rarely sub-acid, in which case if a piece of reddened litmus paper be immersed in the mucous deposit, it always evinces the presence of alkaline properties in the latter. Even when a very small quantity of mucus exists in urine, its presence may be made out by microscopic examination. Sometimes a kind of web presenting the rudiments of an imperfect globular structure is observed floating in the drop of fluid examined. When this is the case it is not unfrequent to find crystals of the triple phosphate or of uric acid entangled in the web of mucus. More frequently, however, globular particles of mucus are found free and floating in the urine.

True mucous globule.—This is generally somewhat smaller than the pus particle, being about one two-thousandths of an inch in diameter. With a low magnifying power, as

with an object-glass of half an inch focus the globules appear smooth and diaphanous, but with a glass of one-seventh or one-eighth of an inch, the surface of the particle appears distinctly granular, although not in so marked a manner as the pus particle. It is extremely difficult to distinguish the pus from the mucous particle, and even by comparison it is not easy, and certainly in many cases quite impossible, to distinguish between them. The fact of the urine not being albuminous, and of the particles not so readily evolving their nuclei when treated with acetic acid, nor of being dissolved on the addition of ammonia, will help in distinguishing between the pus and mucous particles.

Organic globules.—I have, in a paper giving a brief description of the globules found in urine (Guy's Hospital Reports, October 1842), ventured to give this name, as a generic term, to a series of very ill-defined and difficultly-discriminated globules occurring in urine. These appear to present certain differential characters, which prevent their being classed with pus and mucus, but which are not so well marked as to enable us to pronounce definitely on their nature.

Large organic globule.—A globule of frequent occurrence, especially in the urine of pregnancy, of irritable bladder, and of granular degeneration of the kidneys (morbus Brightii). It seldom forms a visible or distinct deposit, but is more generally scattered in the urine so sparingly that not more than a dozen or two are at once visible in the field of the microscope. These are distinguished with great difficulty from the two last-described globules, and perhaps are best known by their not presenting so distinctly a granular exterior, nor so readily evolving their nuclei on the addition of acetic acid. I suspect that this globule is identical with the one described by the French writers as muco-pus. There is a peculiarity in these globules which serves practically to distinguish them from other analogous bodies; depending upon their not undergoing any marked change when the urine is warmed. Thus, if a small quantity of urine containing them is gently warmed in a watch-glass, and a rotatory motion be given to the latter, the organic globules will collect at the bottom, forming a white deposit, which, when the supernatant urine is replaced by water, presents a remarkably glistening, or even crystalline aspect, like a deposit of oxalate of lime. On examining a portion of this by the microscope, the globules will be found unaltered by the heat, and perfectly free, so as to roll over each other on inclining the glass on which they rest.

I have occasionally observed a variety of this globule which differs in its behaviour with acetic acid from that just described. In its granular exterior, and in most of its pro-

1. The powdered bark yields to water more readily than dry inert matter than when finely powdered (exp. 19)
2. The infection is separated from submerged bark with much greater facility than when being employed for this purpose.
3. The additional expense of bark powdering is avoided.
4. A smaller quantity of water is required.

Pharmaceutical Analysis of Yellow Bark.

Pharmaceutical Inquiry. — **Dec. 1.** — **1st Maceration.** — At the
 (bark) Howard's yellow bark imported
 in 1877, were subpulverized and macerated 24 hours in twice the weight
 (24 parts) of cold distilled water.
 The infusion was transparent, of a
 beautiful deep amber colour, aromatic
 not very bitter, acid to litmus paper.
 (See J. P. 1020).
2d Maceration. — The same bark, no
 more than 12 hours, was macerated
 in 12 parts of cold distilled water.

Maceration.—The same bark, not deprived by pressure of the juice, was again macerated in 24 pints of cold distilled water. The second infusion possessed less of the first, but in a few days it was 5. g 1010. In the same quantity of water 1007.

The period of 24 hours is adopted as a matter of convenience. It will be shown in a subsequent experiment that the bark yields to cold water in 4 hours all that can be taken out in a single maceration.

The object of using so much quantity of water as twice the weight of the matter, which being for the most part a constituent of the tissue, is less than the portions contained in it. The specific gravity of the oil of the same samples varies considerably, the highest I have met with is more exactly 1.010 or 1.011. No. 1. contained — The first

perties, they cannot be distinguished, but when acetic acid is added the globules become more translucent, and the presence of two nuclei is readily demonstrable. These nuclei are not globular, as in the last described bodies, but are crescentic, with their concavities opposed, so that they resemble two menisci seen in section. I confess that I have been inclined to refer these organic globules to the same class as the colourless particles of the blood, in which, from the observations of Mr. Wharton Jones, the character of the nuclei I have described appears to be well marked.

Small organic globules.—I have occasionally discovered in urine, when gently warmed in a watch-glass, a white lustrous but scanty deposit, which, when examined under a power of one-eighth inch, appears to be composed of myriads of absolutely spherical globules, free from all asperities or irregularities of surface. Acetic acid, even on the application of warmth, produces no change in these globules. They are smaller than blood-discs, and very closely resemble in appearance the transparent nuclei of pus particles. Whether this, however, is their true nature, I am quite unable to state.

These minute globules I have but rarely met with; they occurred in the urine of women who were menstruating, and were but transitory phenomena, as they were seldom present in a second specimen.

I have described to you these forms of organic products chiefly for the purpose of drawing your attention to what has been already observed with regard to them. The indications afforded by what I have termed "organic globules" are as yet scarcely known, and probably will remain in an exceedingly unsatisfactory state, until we acquire better means of distinguishing them than we at present possess.

Among the many microscopic phenomena presented by urine, few are more interesting than some observed in diabetic urine. If the urine passed by a diabetic patient be set aside in a tall vessel for a few hours, and the lower layers be examined between plates of glass under a good object glass of 1-8th inch focus, numerous ovoid vesicles will be observed floating in the fluid. These are free from all asperities, and are distinguishable by their oval form from other organic deposits. These are what are termed globules of ferment, analogous to those found in all fermenting fluids; and are readily detected in the urine within eight hours of its being passed, if it be placed in a tolerably warm place. Whenever you meet with these oval bodies, you may be confident that the urine contains sugar. They are in fact spores of a peculiar confervoid organism, which is rapidly developed in saccharine fluids about

to undergo various fermentation. In 24 hours after diabetic urine is passed, a cloud rises to the surface, and soon after a distinct pellicle is formed: if this be examined under the microscope you will find it composed of the ovoid bodies referred to, mixed with minute jointed, single, or branched tubes. These are the young plants of a minute conferva, the *torula cerevisiæ*.

FIG. 19.

In a day or two this torula undergoes a change; the tubes break up, and a copious deposit of fresh spores forms on the sides and bottom of the vessel. If these be placed in a solution of sugar, they will rapidly germinate, and produce fresh crops of confervæ. Contemporaneously with the development of these minute confervæ the elements of the sugar and of water undergo a metamorphosis, and alcohol with carbonic acid are the results.

You will very frequently, in your microscopic examination of urine, meet with certain organised particles, which are derived from the epithelial layers of the mucous membrane of the urinary passages. These are sometimes merely an amorphous debris, in which any definite structure is made out with great difficulty. You will scarcely, however, meet with a specimen of this kind in which you will not succeed in detecting epithelial cells, cylinders, or scales, sufficiently perfect to permit their being readily identified. Of the various forms of epithelial tissue, the most frequently met with is, perhaps, the oval nucleated cell; this often appears well defined, and is a very beautiful object, resembling in outline a shield with a central boss. I have found, mixed with these, roundish cells of considerable size, distended with fluid, and appearing perfectly distinct under a low power ($\frac{1}{2}$ inch focus). You will scarcely examine a specimen of urine passed in the morning on rising from bed in which you will fail to detect some debris of epithelium, and this becomes greatly increased if the patient is labouring under any inflammatory or irritable state of the mucous membrane of the urinary passages.

I have thus, gentlemen, brought to a close my remarks on the chemical and pathological characters of urinary deposits: I might

have occupied your time during several more lectures, had I not wished to avoid making the subject tedious to you by being too prolix. I have endeavoured to point out to you those characters by which you will readily succeed in distinguishing the different deposits which are met with in urine, and which are no longer to be regarded as a mere piece of idle curiosity, but really of great importance in directing our diagnosis and treatment of some of the most important diseases to which our race is subject. In conclusion, I wish to direct your attention to a tabular analysis of the most prominent characters presented by the saline urinary deposits, including all those in the first two classes which have fallen under my own observation. This will, I hope, serve as a useful index to the detailed account of the deposits contained in these lectures, and assist you in their discrimination of them at the bed-side.

ON YELLOW BARK.

(To Sir Henry Hallford, Bart.)

SIR,

I AVAIL myself of the kind permission you have given me on former occasions to address to you some observations on yellow bark, and on the concentrated cold infusion which I have for many years prepared under the name of *Liquor Cinchonæ cordifoliæ*, trusting that you will not consider I trespass too much on your indulgence.

Five years ago I had the honour of presenting to the Royal College of Physicians a paper, which was read on the 4th of May, 1838, containing some remarks on this subject.

The repeated assurances I have received from high medical authorities of the superiority of the concentrated cold infusion, and my own analyses and observations, have long satisfied me that it is a more perfect and efficient preparation of cinchona than any other now in use.

The value of yellow bark has been too generally and too exclusively attributed to the quinine it contains. It has ever been an object with me to *preserve unbroken that natural union by which several active principles are often combined in the same plant*. Every day's experience convinces me that neither the separation of certain principles, nor the more ordinary pharmaceutical operations by decoction, infusion, and spirituous digestion, furnish

us with medicines of equal value with those which are obtained by simple maceration in *cold distilled water*, which takes up from plants, with few exceptions, all their medicinal properties, whether acid or alkaline, gummy or resinous, bitter or astringent.

Yellow bark is produced by an undetermined species of *Cinchona*. In the London Pharmacopœia it is still ascribed to the *Cinchona cordifolia*, a native of Bogata, the bark of which was erroneously supposed by Mutis to be identical with it. Genuine yellow, or as it is sometimes termed royal yellow bark, is not a native of Spanish Guiana, but of the provinces of La Paz and Potosi in Bolivia, or Upper Peru, and is brought to us not from Carthagena, but from Arica and Lima.

The drug merchants at Cadiz state that it is not conveyed to Lima by sea, like the other barks, but is found only at the distance of two or three hundred leagues from the capital, and conveyed over steep and almost inaccessible mountains. (Relph's Inq. into the Med. Efficacy of Yellow Bark, 1794, p. 69.)

The earliest notice that I am acquainted with of this bark is to be found in Pomet's History of Drugs, written in 1694. This old but valuable author mentions another kind of quinquina, or Peruvian bark, which comes from the mountains of Potosi, and is browner, more aromatic and more bitter, than the barks about Loxa, but abundantly scarcer than any of the rest.

It seems, however, to have fallen into disuse, and to have been forgotten, till about 1788 or 9, when a parcel having arrived at Madrid, and having been found on trial more efficacious than the pale sort, was immediately bought up by the king's order for the use of the Royal Family, and hence was distinguished by the name of royal yellow bark. Further experiments in Spain and France were attended with the same success. Murray, in his Apparatus Medicaminum, published at Göttingen in 1792, mentions (Vol. 6, p. 180), that a bark had recently been brought from London under the name of *cortex chinæ vel chinchinæ regius*: that he was unacquainted with its native country, but that in the year 1790 he had seen it at Frankfort on the Main, where it was sold for 16 dollars the

pound, and subsequently at Wisbaden. He had also received the same bark from another quarter under the name of *cortex chinæ flavus*, and had seen specimens from Amsterdam, where it bore the name of royal yellow bark. *Cortex chinæ regius flavus*. Murray's description corresponds with our yellow bark, and he adds that the Frankfort physicians found it very superior in efficacy to the common Peruvian bark, especially in intermittents.

In 1793 the Spanish register ship St. Jago, having been captured by a French privateer, was retaken by Admiral Gell's squadron off Cape Finisterre in the Bay of Biscay, and on its arrival in England was found to contain a great many chests of this bark of first rate quality. The following year it was strongly recommended by Dr. Relph, of Guy's Hospital, as promising to surpass all the other kinds of Peruvian bark then employed in medicine."

Pharmaceutical Analysis of Yellow Bark.

Exp. 1.—1st Maceration.—28 lbs. (avds.) Howard's yellow bark imported in 1837, were subpulverised and macerated 24 hours in twice the weight (56 pints) of cold distilled water.

The infusion was transparent, of a beautiful deep amber colour, aromatic and very bitter, acid to litmus paper, and of s. g. 1020.

2d Maceration.—The same bark, not having been deprived by pressure of the water absorbed, was again macerated 24 hours in 24 pints of cold distilled water. The second infusion possessed the properties of the first, but in a far less degree. S. g. 1010.

3d Maceration.—In the same quantity of water. S. g. of the infusion 1007.

4th Maceration.—S. g. of infusion 1004.

5th Maceration.—S. g. 1000. This infusion was nearly colourless, and possessed scarcely any aroma, bitterness, or astringency.

Obs.—The method adopted in this experiment is the same which is invariably employed in making the cold infusion from which the liquor cinchonæ is formed, except that to form the liquor the operation is not continued beyond the third maceration.

The bark which I employ is not *finely powdered*, but only *subpulverised*, for the following reasons:—

1. Subpulverised bark yields to water as much quinine and less inert matter than when finely powdered (exp. 19.)

2. The infusion is separated from subpulverised bark with much greater facility, pressure not being employed for this purpose:

3. The additional expense of finely powdering is avoided.

4. A smaller quantity of water is sufficient.

The period of 24 hours is adopted as a matter of convenience. It will be shewn in a subsequent experiment (18) that the bark yields to cold water in 3 or 4 hours all that can be taken up in a single maceration.

The object of using so small a quantity of water as *twice the weight* is to avoid taking up the gummy matter, which being for the most part a constituent of the *tissue*, is less soluble than the *secretions* contained in it.

The specific gravity of the infusion of different samples varies considerably; 1020 is the highest I have met with: it is more frequently 1010 or 1012.

Exp. 1, continued.—The first infusion was slowly evaporated in a Wedgwood dish over a water-bath, to the consistence of syrup, s. g. 1200; care being taken that the temperature did not exceed 140. During the evaporation, and towards the close, a dark granular matter separated, destitute of taste and smell. (A.)

The concentrated infusion separated and left at rest for more than a week, did not undergo the slightest change. It was aromatic and intensely bitter, and readily blackened a weak solution of tinct. ferri. mur.

The second infusion during concentration let fall much red granular matter (A), and subsequently, when left at rest, formed a gummy precipitate containing evident crystals. (B.)

The third infusion underwent similar changes, yielding after concentration a still larger quantity of gummy precipitate.

The three infusions concentrated to s. g. 1200, and separated from the gummy and red granular matter, were mixed, and weighed 5lbs. 11 ounces.

Obs.—A much larger quantity of red granular matter usually falls from the latter, than from the earlier infusions probably because that which is obtained from the tissue is less soluble than that which is contained in the cells and is taken up during the earlier macerations.

In the quantity of liquor, and the specific gravity of the first infusion, Howard's bark of 1837 is nearly equal to that taken from the St. Jago; but the quality obtained from barks imported in other years, equally good in *appearance*, and treated exactly in the same way, is much less.

Horner's bark, imported in 1834-6, yielded 4 lbs. 7 ounces, and a sample of my own of another importation yielded only 2 lbs. 9 ounces.

Exp. 2.—Two ounces of the concentrated infusion, s. g. 1200, were diffused in eight ounces of distilled water. The mixture was very bitter and aromatic. Tr. ferri mur. rendered it quite black. The mixture was acidulated with pure muriatic acid, and saturated with magnesia, and the precipitate was washed and dried. The supernatant fluid was scarcely bitter, and tr. ferri mur. produced very little blackness. The dried magnesian matter was boiled in alcohol, s. g. 815, and the solution decanted. The spirit was distilled off, except one ounce, which was left to evaporate spontaneously. The mass remaining at the bottom of the dish was dissolved by dilute sulphuric acid carefully added till it was in the slightest degree in excess. The solution was slowly evaporated, and crystals formed of sulphate of quinine. These crystals were dissolved in distilled water, and ammonia being added a white matter fell (*quinine*), weighing 96 grains.

Obs.—It appears from this experiment that 5 lbs. 11 ounces of the concentrated infusion contain within a few grains 10 ounces of quinine, which is therefore the quantity taken up by cold distilled water from 28 lbs. of yellow bark.

Exp. 3.—1 lb. (avds.) of yellow bark subpulverised was macerated all night over a water bath in 4 pints of distilled water acidulated with sulphuric acid. The liquor was strained through gauze. The bark was then boiled half an hour in two successive portions of acidulated water, and the liquor strained, pressure being used to displace the fluid.

The three liquors were mixed and oversaturated with fresh slacked lime. The mixture was boiled and filtered, and the precipitate dried and boiled in two portions of spirit of wine; the filter and the matter remaining on it being also washed and boiled in an ad-

ditional portion of spirit of wine. The spirit filtered and distilled left of *quinine* 229 grains.

The refuse bark was finally macerated several hours in water acidulated with acetic acid, to which it imparted no colour. The infusion was not precipitated, and only slightly coloured by the addition of ammonia.

Obs.—28 lbs. therefore contain about 14 ounces of quinine. Experiments 1 and 2 show that the liquor prepared from 28 lbs. contains nearly 10 ounces of this. The remainder of the quinine not taken up by the cold water may be subsequently separated by acetic acid (see experiment 13), and added to the liquor, which will then contain the whole of this constituent. But this addition will scarcely repay the expense of the operation.

The quantity of quinine in different samples varies considerably, but the reduction of the specific gravity of the liquor to 1200 ensures a *uniformity* in this respect which cannot be obtained by the simple infusion or decoction of a definite quantity of bark.

Exp. 4.—One ounce of the liquor was dried and incinerated; the incineration was slowly accomplished, the matter burning like leather. The ashes weighed 37 grains.

The 37 grs. were boiled in distilled water, and the nitrates of baryta and silver indicated the presence of *sulphuric and muriatic acids* in the solution. The residuum was further dissolved in distilled water, acidulated with pure muriatic acid; and ferrocyanate of potash, ammonia, and bicarbonate of soda, detected *iron, alumina, and lime*. The residuum was *silex*.

Obs.—I have generally found the muriates most abundant in inferior samples of bark.

Exp. 5.—120 grs. of the red granular precipitate (A), were macerated in 4 oz. of alcohol. The spirit was deeply tinged. A second portion was slightly tinged. The residuum dried weighed 73 grs., 47 grs. having been taken up by the spirit. The 73 grs. were placed in distilled water, and liquor potassæ was carefully added. Turmeric paper indicated no free alkali till the quantity added amounted to 2 drms. The alkaline liquor took up 33 grs., leaving 40 grains undissolved.

Obs.—This precipitate appears to consist chiefly of tannin.

Exp. 6.—One ounce of the same matter was incinerated; the ashes weighed only 19 grs. Ten grains of this being taken up by distilled water gave to the nitrates of silver and baryta traces of *sulphuric* and *muriatic acids*. The residuum, boiled in water acidulated with pure muriatic acid, gave to ferrocyanate of potash, ammonia, and bicarbonate of soda, a little *iron*, *alumina*, and *lime*.

Exp. 7.—The gummy precipitate (B) as it dried formed beautiful crystals in considerable quantity. A portion of it was washed in spirit of wine to remove the *tannin* and *gummy* matter. The remaining mass of crystals was of a pale yellow colour, in appearance resembling sulphate of quinine. The crystals were dissolved in distilled water, and oxalic acid carefully added caused an abundant white precipitate (L). The supernatant liquor was not disturbed by the further addition either of oxalic acid or of lime-water, and therefore contained neither. It was evaporated to the consistence of syrup, and gradually deposited crystals for many weeks. These crystals, consisting of the peculiar acid of bark commonly called *kinic acid*, are perfectly colourless and very acid. They dissolve quinine readily, even without heat, forming with it a salt which does not redden litmus paper.

The precipitate (L) was dissolved in pure muriatic acid, the solution filtered, and lime precipitated by carbonate of soda.

Obs.—Kinate of lime does not appear to be an important constituent of bark, for inferior bark contains much the largest quantity.

Exp. 8.—Another portion of the gummy precipitate (B) was placed in distilled water, and the clear fluid poured off. The insoluble residuum (C) was a light powder, of a brownish red colour, scarcely bitter, and almost tasteless. 20 grains of it were incinerated; the odour was very fragrant, and much resembled castor: 1½ grs. only remained.

Another portion of C was almost entirely dissolved in liquor potassæ and liq. ammoniæ, and tinct. ferri mur. added to the filtered solutions, formed a deep green colour, which soon became black. The small portion not dissolved by the cold alkaline solutions was *waxy*. Boiling ether

dissolved it, and water precipitated it from its solution. The *waxy* matter readily inflamed, burning with much smoke.

Exp. 9.—All the precipitates from 28 lbs. of yellow bark were placed in dilute sulphuric acid for several hours, and a little heat applied. The filtered solution was saturated with lime, and boiled over a water-bath. The residuum was then dried, boiled in spirit of wine, and the spirit distilled off, excepting 2 drs. which, being evaporated to dryness, left of *quinine* 22 grs.

Obs.—The precipitates, therefore, contain *quinine* and *lime*, combined with *kinic acid*, *gummy matter*, *tannin*, and *wax*.

Exp. 10.—The cold infusions tested with iodine did not indicate a trace of starch. A portion of the residual bark exhausted by 5 cold macerations was placed in fresh distilled water, and heat applied.

The colours produced by the addition of tr. of iodine at the different temperatures were as follows:—

At 135 deg.	red
140	„ pale violet
150	„ full violet
160	„ deep purple
170	„ the same.

The bark was now removed and washed; a fresh portion of water was added, and the temperature raised to 190°. Scarcely a trace of starch remained.

Obs.—The *starch* is taken up between 140° and 170°.

Exp. 11.—The residual bark, after 5 cold macerations (ex. 1), was *boiled* half an hour in *distilled water*; the fluid was turbid. While hot it was of a reddish yellow colour, but became milky when cold. A slight bitterness and acidity were perceptible, and a little blackness was produced by the addition of tr. ferri mur.; the specific gravity was .999. One half of this fluid was acidulated with sulphuric acid and boiled, and continued acid after boiling. It was saturated with lime, boiled, and filtered; and the residuum boiled twice in spirit of wine. The spirit filtered and withdrawn left of *quinine* 56 grs.

The other half of the fluid was strained and evaporated. It continued turbid, but no precipitation took place. When reduced to a dry state, it curled up like a layer of starch, and weighed only 1½ oz.

1 oz. of this matter was incinerated without flame. A little aroma escaped. The ashes, 50 grains, were boiled in distilled water, which took up 16 grs., leaving 34 undissolved.

The solution, tested with the nitrates of silver and baryta, and tartaric acid, indicated the presence of *sulphuric acid*, *muriatic acid*, and *potash*.

The 34 grains were almost entirely dissolved in water acidulated with pure muriatic acid. Ferrocyanate of potash, ammonia, and bicarbonate of soda, indicated *iron*, *alumina*, and *lime*.

Obs.—The sp. gr. of the decoction after cold maceration is sometimes above, but more frequently below, 1000. When the sp. gr. rises above 1000, it is chiefly owing to the presence of a little gum. The starch is lighter than water. The quantity of quinine taken up from 28 lbs. of bark by boiling distilled water, after 5 cold macerations, is 112 grs.

Exp. 12.—The residual bark from Exp. 11. was boiled half an hour in distilled water *acidulated with sulphuric acid*. To the strained liquor, still acid, was added new burnt lime in powder. The mixture was boiled half an hour, and the fluid strained off through hempen bags. The collected matter was thoroughly dried, and boiled half an hour in 12 pints of rectified spirit. The spirit was passed through paper, and the refuse washed with a second portion of spirit, which was added to the first. The spirit was then brought over by distillation, and left in the *balneum* 3 oz. 280 grs. of *quinine* resembling wax.

Exp. 13.—28 lbs. of yellow bark having been subjected to 6 macerations in cold water until the infusion ceased to gain any increase in specific gravity, were macerated in water *acidulated with acetic acid* (specific gravity of vinegar 1004).

In half an hour the sp. gr. of the fluid was 1001, and ammonia gave a large precipitate. In 1 hour the sp. gr. was 1006. In 4 hours it still remained at 1006.

The fluid was drawn off and a fresh portion of acidulated water added. This operation was repeated 3 times.

The fluids were mixed, and precipitated by ammonia. The precipitate was placed in dilute acetic acid, but a considerable portion, 370 grs. remained undissolved.

The acetic solution was carefully precipitated by oxalic acid, and the precipitate, when dry and burned, (lime) weighed 152 grs. The fluid from which the lime had been separated by oxalic acid was then precipitated by ammonia, and the precipitate, when dry, (*quinine*) weighed 2 oz. 300 grs.

The 370 grains not taken up by acetic acid were macerated 24 hours in 1 pint of cold rectified spirit, sp. gr. 838. The spirit took up 201 grains, and became of a dark colour, leaving 169 grains undissolved.

The 169 grs. were boiled in spirit 10 minutes. The filtered fluid was dark. The insoluble refuse weighed 114 grs., having lost 55.

The two portions of spirit were mixed, and the spirit being separated by distillation in a glass retort, left 3 dr. 3 grs. of a dark matter (*tannin*) which produced an intensely black colour with tr. ferri mur.

The insoluble refuse, 114 grs., was burned, and left 6½ grs. of ashes extremely light and bulky.

Obs.—Exps. 12 and 13 show that after cold water has taken up the whole of the quinine and other soluble matters deposited in the cells of the bark, there may still remain a further portion of quinine, together with lime and tannin, so intimately united with the tissue itself as to be only separable by means of acids.

This portion of quinine, when completely separated by sulphuric acid, amounted, in this instance, to 3 oz. 280 grs.

Acetic acid takes up this second portion of quinine less perfectly than sulphuric acid, but the quinine is separated from acetic acid with greater facility and less expense by means of ammonia without the use of spirit. The quinine thus obtained is generally combined with more or less tannin, which it is extremely difficult to remove from it. There is, however, no necessity to do this if the quinine is to be added to the liquor, of which tannin is an important constituent. The combination is easily effected by dissolving the quinine and tannin in a little dilute acetic acid. I have before alluded, under Exp. 3, to the expense of this part of the operation, and I may add that I have sometimes found that cold water has taken up *the whole, or nearly the whole*, of the quinine, so that the

residual bark has yielded little or none to acetic acid.

I shall here introduce two experiments to show more clearly the power of acetic acid as a solvent of quinine.

Exp. 14.—2 oz. of Howard's yellow bark, subpulverized, were placed in 14 oz. of distilled water and 2 oz. of *distilled vinegar* for half an hour, and frequently stirred. The fluid was filtered through washed white paper, and precipitated with ammonia so long as a creamy separation took place. The precipitate was very abundant. The colourless supernatant fluid, being treated with more ammonia, gave a yellow precipitate resembling powdered gamboge. The two precipitates mixed, weighed, when quite dry, 25 grs.

The bark was again macerated for half an hour in 7 oz. of distilled water and 1 oz. of distilled vinegar, and the fluid filtered through washed white paper. Ammonia being added as before, a considerable precipitation ensued, but much less than the first. The supernatant fluid was red, and the precipitate was tinged with the same colour. It weighed, when dry, 7 grs.

A third maceration was made with 7 oz. of distilled water and half an ounce of distilled vinegar, and ammonia added to the filtered fluid as before. The precipitate was a deep red colour, as well as the supernatant fluid. The former, when dry, weighed 4 grs.

The same operation was repeated with 2 drs. of distilled vinegar. The precipitate and fluid were quite red. The former weighed 3 grs. A fifth maceration with 1 drachm of distilled vinegar gave only half a grain. A sixth maceration with half an ounce of distilled vinegar yielded 0. The residual bark was boiled ten minutes in water acidulated with sulphuric acid. The strained fluid was saturated with magnesia, and the magnesian matter dried and boiled in rectified spirits for several minutes. The spirit being withdrawn left of quinine quite dry, barely 1 gr.

The precipitates, 1-5, weighing 39½ grs. were placed in half a pint of distilled water, and acetic acid added to dissolve the quinine; the filtered fluid was carefully precipitated by ammonia, and the quinine, when collected and dried, weighed 23 grs., to which may be added 2 grs. for the quinine remaining on the filter—in all 25 grs.

The 23 grs. were incinerated with

difficulty, burning like leather. Half a grain only remained.

The last experiment was repeated as far as the third maceration with 4 oz. of bark; and the quinine subsequently separated from the residual bark by sulphuric acid weighed 3½ grs., which nearly agrees with the former result.

Exp. 15.—2 oz. of Howard's yellow bark were boiled ten minutes in 1 oz. of distilled water acidulated with *sulphuric acid*. The fluid was strained, and the bark boiled ten minutes in a second portion of acidulated water. The decoction was fully saturated with magnesia, and the dried magnesian matter boiled ten minutes in two successive portions of rectified spirit. The solutions were mixed, and the spirit being withdrawn left 26 grs. of quinine.

Obs.—The colourless precipitate from the first acetic solution was quinine nearly pure; the second, of a gamboge colour, chiefly tannin; the subsequent precipitates consisted almost entirely of tannin. The quinine taken up by sulphuric and acetic acids was as 26 : 25.

Exp. 16.—2 oz. of yellow bark subpulverized were macerated several days in 1 oz. of spirit of wine. The spirit was brought over, and left a small quantity of dry *inflammable extract*, consisting of *resin* and tannin.

Exp. 17.—1 lb. of yellow bark was macerated in 1 gallon of distilled water 2 hours, and then placed in a still well luted, and water added to prevent burning. 1 gallon was brought over, sp. gr. 1000, yielding the *odour* of the bark, and a little *essential oil* was detected on the surface. When the still-head was removed, the odour was very strong.

It appears from these experiments that yellow bark contains—

A peculiar acid, Exp. 7.
Quinine, Exp. 2, 3, 9, 11, 12, 13.
Tannin, Exp. 1, 2, 5, 8, 13.
Aromatic principle (*essential oil?*),
Exp. 17.
Lime, Exp. 4, 6, 7, 11.
Potash, Exp. 11.
Alumina, Exp. 4, 6, 11.
Muriatic and sulphuric acids, Exp. 4,
6, 11.
Iron, Exp. 4, 6, 11.
Silica, Exp. 4.
Wax, Exp. 8.
Resin, Exp. 16.

Gummy matter, Exp. 7.

Starch, Exp. 10, 11.

Woody tissue.

The following experiment was made to ascertain the length of time required for the cold infusion.

Exp. 18.—Half a pound of yellow bark subpulverized was placed in two pints of cold distilled water. In five minutes the fluid was acid to test paper. In twenty minutes it was manifestly acid to the taste.

In half an hour the filtered infusion was of a beautiful straw colour, fragrant, and agreeably bitter, sp. gr. 1004½. Tr. ferri mur. produced a delicate grass green tinge, and a little separation.

Tr. of galls gave a slight brownish white disturbance; tartarized antimony, a whitish precipitate: *oxalic acid*, no perceptible change.

In one hour the fluid was a deeper straw colour, more bitter, but not unpleasant. The bitter remained long upon the tongue, sp. gr. 1006½. Tr. ferri mur. produced a deep green colour, and a larger precipitate; tartarized antimony and tr. galls a great disturbance; *oxalic acid* no change.

In two hours the bitter was much more intense, and the test paper was made quite red. Sp. gr. 1009. Tr. ferri mur. produced instantly an opaque green, and the subsequent precipitation was still greater. The effect of tartarized antimony and tr. of galls was much the same as before. *Oxalic acid* produced a great disturbance. The precipitated matter was a yellowish white.

In three hours test paper had the same appearance; the taste was very bitter and permanent; sp. gr. 1011½. Tr. ferri mur. produced the same effect as in the first trial. The other tests as before.

In four hours, sp. gr. had not increased. Tr. ferri mur. and the other reagents produced the same changes as in the last.

In five hours and a half, sp. gr. was still 1011½. Tr. ferri mur. produced a dull green, but very little precipitate.

In six hours, sp. gr. the same. Tr. ferri mur. gave a still paler green, and no opacity or precipitation.

Two pints of cold distilled water were now added, which reduced the specific gravity of the fluid to 1006. At the end of one hour, sp. gr. was still 1006. Nothing therefore had been taken up by the additional water.

Obs.—The quantity of water employed in this experiment was four times the weight of the bark, on account of the small quantity of bark experimented upon.

The most agreeable cold infusion, and that which is most likely to suit a weak stomach, is formed in the first half hour. The sp. gr. continues to increase to the end of the third hour, after which little or nothing is gained by continuing the maceration in the same fluid.

If the fluid is now poured off, and a fresh proportion of water added, the maceration may be repeated for the same time.

The acid, quinine, tannin, and aromatic principles, are taken up rapidly from the commencement of the operation; the lime somewhat later.

The tannin taken up by the water apparently forms subsequently a new combination, which diminishes its effect on salts of iron; for after six hours' maceration, the infusion, which had previously given a copious precipitate with tr. ferri mur., ceased to do so, though it acquired the green colour.

Exp. 19.—1 lb. of finely powdered bark was macerated one hour in four pints of cold distilled water, and the infusion filtered. As the filtration proceeded, more distilled water was added four successive times, until the sp. gr. of the infusion was reduced to 1000.

The bark was then boiled ten minutes in water, and the strained decoction slightly acidulated with sulphuric acid and boiled. At the termination of the boiling the decoction was still acid. The fluid was again strained and saturated with lime; and the residuum dried and boiled fifteen minutes in half a pint of spirit of wine. The spirit being abstracted from the filtered fluid, left, of quinine, 4 grs.

The bark was next boiled twenty minutes in water acidulated with sulphuric acid, and the strained fluid saturated with lime. The residuum was dried and boiled in two successive portions of spirit. The spirit mixed, and brought over by distillation, left, of quinine, 59 grs.

The same operation was performed by cold maceration with 1 lb. of subpulverized bark, till sp. gr. of infusion was 1000. The quinine subsequently taken up by boiling water weighed 4 grs.; and the quinine taken up by

boiling water acidulated with sulphuric acid weighed 58 grs.

It follows, then, that the quinine taken up by cold infusion must also have been the same in the two cases, and consequently that no advantage is gained by reducing the bark to the state of powder.

The conclusions to be drawn from these experiments are—

1. Bark will yield to *cold distilled water* all its constituents except starch and woody fibre, some earthy salts, and a small portion of tannin and quinine, which can only be separated from the tissue by means of an acid.

2. 28 lbs. of good yellow bark will yield from 5 to 6 lbs. of concentrated liquor, sp. gr. 1200, containing about 10 oz. quinine; the aroma, and the greater part of the tannin and iron, and the peculiar acid of bark, of which only a small portion is lost, forming an inert salt with lime.

3. To form this liquor it is only necessary to subpulverize the bark, and macerate it from four to six hours in twice its weight of cold distilled water, repeating the process twice, or at most thrice: to concentrate the infusions over a water bath to sp. gr. 1200, and allow the liquor to deposit the gummy matter and so much of the tannin as it cannot retain in solution.

To separate any gum that may still remain in the liquor, and to prevent any decomposition, proof spirit is added to it, until the sp. gr. of the liquor is reduced to 1100. The quinine still remaining in the bark, may, if it be thought desirable, be separated by acetic acid, and precipitated from its solution by ammonia; and being redissolved in a small quantity of dilute acetic acid, may be diffused in the liquor.

The advantages of this medicine are—

1. That it contains not one, but all the active principles of yellow bark.

2. That the greater part of the quinine is preserved *in its natural state* in combination with the peculiar acid of bark, in which it is more soluble than in sulphuric acid.

3. That the active principles *have undergone no change*, either from exposure to too great heat, as in the decoction, &c. or by being brought into too close contiguity, as in the extract, in which secondary formations take

place to so great an extent that water is incapable of redissolving it.

4. That, containing no starch and little gum, it will remain unaltered for a great length of time.

5. That the quantity of spirit contained in a dose is too small to be objectionable.

6. That it is a convenient, agreeable, and elegant medicine, miscible with wine or water in any proportion.

On its merits as a therapeutic agent I forbear to enter. I will only add, that whatever yellow bark can accomplish will be best performed either by the recent cold infusion or the concentrated liquor. The latter not only agrees with the stomach, when irritation and nausea are produced by the disulphate of quinine, but it not unfrequently succeeds in obstinate periodic and cachectic diseases when the disulphate of quinine has failed. But the liquor cinchona has been so long before the profession, and is so extensively employed, that it requires no observations of mine to prove its efficacy. My object, in the present paper, is rather to make more generally known the exact method of preparing it, and to direct attention especially to those peculiarities in the process on which its elegance and efficacy chiefly depend.

The above is offered as a *pharmaceutical analysis* of yellow bark; a *chemical analysis* I hope to have the pleasure of presenting before long, as well as a similar series of experiments on the cinchona lancifolia.

Moorfields, April 1843.

CASE OF ILEUS.

(For the London Medical Gazette.)

We beg to offer the accompanying account of a case of ileus to the Editors of the MEDICAL GAZETTE, for insertion, if approved, in their periodical; for—

1st. We may learn from it the advantage of adopting, in cases in which no rational plan of treatment presents itself, the *methodus expectans*, or of husbanding up the vital powers to support any providential efforts at recovery which may be made in the system.

2dly. It was daily observed that, when the intestines were loaded to fullness, the *passio iliaca*, or reversed ac-

tion of the intestines, was uniformly accompanied by spasm or cramp of those muscles forming the abdominal parietes; so that the external surface or skin was corrugated and irregular, in like manner as is visible on the larger muscles of the extremities when under the influence of cramp; and this continued until the fæcal matters were brought up by the stomach.

3dly. We learn the length of time the body can be supported by the absorption of its own substance, after so serious an attack of disease, and such complete obstruction, together with material derangement, of a vital function.

D. R. & DAVID R. M'NAB.

Epping, April 20, 1843.

A——B——, has had occasionally, for the last five years, pain in the right hypogastric region; and three years ago had an illness, with griping pain in the abdomen.

March 12, A.M.—Has griping pain in the abdomen, sickness, and desire to go to stool.

℞ Hyd. Chlor. gr. iiss.; P. Opii, gr. ʒ, stat. sum.

℞ Haust. Rhei, et Mag. Carb. hor. j. post hac sum.

7 o'clock P.M.—No evacuation of the bowels.

℞ Haust. Sennæ Co. stat. sum.: vomited. Administ. Enema Salis et Sap.: with this came away much hard fæcal matter.

13th.—Pain violent; vomiting and constipation continue; abdomen tympanitic; pain rather relieved by pressure. During the paroxysms of pain the pulse very small, and extremities cold. Tongue milky and dotted.

Capiat. Mist. Ol. Ricini, ex mucilag.: vomited again.

℞ Ol. Ricini, ʒss. 6tis hor. sum.

℞ Hyd. Chlorid. gr. j. hor. ij. post Ol. Ricini, et 6tis hor. sum.

Balneum calidum bis terve die. Dry heat to the abdomen.

P.M.—Administratur enema Ol. Terebinth. ℞ Linim. Hyd. Co. abdom. infricand.

14th.—Abdomen tender and tympanitic; vomiting and constipation continue.

℞ Hirudin. xij. abdom. applicand. Baln. calid.

To allay the violent paroxysms of colic pains—

℞ Morphine Acet. gr. ʒ, 3tis hor. ad tert. vic. sum.

P.M.—℞ Mag. Sulph. ʒj. 3tis hor. sum.

15th.—Leeches were again applied to the abdomen, and a blister, with a repetition of blue pill and morphia.

16th.—Stercoraceous vomiting came on; and from 16th to 31st, to produce evacuation of the bowels, besides injections, the following were prescribed:—

1.—℞ Hyd. Chlorid. gr. x.; Morphine Acet. gr. j. M. ft. massa in pil. iv. div. cap. j. 6tis hor.

2.—Croton oil enema, and croton oil in the form of a pill, every four hours, by which increase of pain and sickness were produced, and the matter vomited was in colour dark-green.

3.—Ox gall, by injections and as pills, to ʒiss.

After which remedies the system was supported by occasional beef-tea injections, effervescing medicine, brandy and water, and yoke of egg, &c.

The abdomen was vastly distended and tympanitic; vomiting and constipation continued; emaciation extreme.

The tongue, at first milky and dotted, became gradually furred, till redness, appearing as a streak in the centre, spread over the whole tongue, which was moist and dry according to the morning and evening changes of the typhoid symptoms.

Pulse variable, as affected by the remedies.

Mind at first very collected, and perceptions unusually quick; latterly much sopor, after which delirium followed, until the senses could be quite roused.

April 1st.—Passed involuntarily a large quantity of urine.

2d, 5 P.M.—Tongue still dry; pulse quick and sharp.

6 P.M.—At length, after a period of twenty-one days, two evacuations were passed from the bowels, yellow, and of thick gruel consistence. Pulse much softer.

Admin. enema sap., which was followed by a large evacuation like the above.

℞ Haust. Sod. Tart. Efferv.

3d.—No sickness; appetite returned.

4th.—℞ Quinæ Disulph. gr. j. bis die sum.

8th.—Tongue paler and moist; pulse soft and quick. Diet: port wine or

brandy and water, broth, mutton chops, eggs, bread and milk, &c.

Sleeps frequently night and day. Mind listless and dull. Temper cross and self-willed. He has continued to improve.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

MEDICAL EDUCATION.

THE practical division of the profession into two great classes, those, namely, who can afford to wait, and those who cannot—adverted to in a former number—produces also a difference, chiefly as to literary qualifications generally attained by each; and all that the State seems bound to do is to fix a minimum of the required professional education. In contending for a high standard of general education for all who enter the profession, no new thing is imagined. An *equally* high standard for all would be new, but there would be no harm in the novelty. What was the case formerly, and what is the theory at present? Two neighbours of the middling class send their sons to the same school—Eton, Harrow, Westminster, or a good private establishment. One goes to College, graduates in arts, and subsequently in medicine; comes to London, and studies the practice of his profession in the hospital and the lecture-room; gets, it may be, appointed to a public institution; spends his leisure in the pursuits of literature, science, or travel, and in the society of the gentry who were his companions at school and college; takes not a single fee for five years or more, and then gets gradually into practice as a physician, occupying a place more or

less distinguished, according to his talents or opportunities. The other leaves school at 14 or 16, is bound apprentice to a general practitioner, spends five years in dispensing; and if he have a good master, or watchful parents, in profitable study of elementary works. At 19 he comes to town; spends two or three years at the hospital and lectures; passes his examination at 22, and becomes a general practitioner. What has made the difference between these two young men? What has made the parents of the latter select for him this course instead of the other? Not the mere difference in expense between a College education and a high apprentice-fee; but the difference between the prospect of his getting profitable employment soon instead of late. The one could afford to wait; the other could not. But how was the immediate return obtained? Partly, no doubt, at least in former times, by the sale of drugs; for in the most private shops there was formerly something of this kind—families were supplied by the family apothecary. Or he might earn a good salary, and hold a respectable station in society as an assistant; but his principal dependence was on dispensing the prescriptions of physicians, and on his practice amongst the middling classes. An apothecary, twenty years ago, could pay his expenses by the prescriptions of physicians; and he often obtained these from houses where he never prescribed himself for the heads of the family.

This source of income is now entirely gone, or very nearly so. The apothecary, highly educated, and no longer the mere dependent of the physician, has become, in fact, a substantive person; but has he, with the professional education of the physician, the means of waiting till these acquirements shall be demanded and paid for by the public? If he has, then, let him be called

what he will, his actual status is the same as that of the physician, and he has ceased to belong to the class who cannot afford to wait. If he has not, then let us see what are his resources. As an assistant, what will he get? For an answer see the advertisements in the medical and daily journals. A Union—he may live *with* that, but hardly *by* it. He must in self-defence open a shop. To do this successfully, he must compete in matter and in manner with the druggist and the grocer; and now of what use is his degree in *literis humanioribus*, his ancient and modern languages, his “treatises *de senectute* and *de amicitia*,” his shorter or longer oration,” his philosophy (that, indeed, is wanted), his algebra?—elegant recreations, and useful withal to fill up the time, together with driving away the flies in summer, and the cold in winter!

It is all very well for men in large practice, where cathartic mixture is made by the gallon, and pills by the gross, to get paid for the medicine made in their shops—*non olet*; but it taints the whole man, inside and out, who has to take pence behind his own counter.

In these days we are not likely to meet with practitioners, empirical or regular, uniting the family experience of seven generations in their own persons, like the one mentioned by Lady M. Wortley Montague; but there are qualities sometimes found among the unlicensed and the unlearned, which command a success denied to the laureated possessors of diplomas. The greatest skill in the practice of our art, and the most substantial marks of public favour, are often found with persons who are woefully deficient in those qualities, whether natural or acquired, which most dignify and adorn the inner man.

Do we, then, undervalue the function

of the druggist as such—or that of the apothecary of days long past? By no means. Still less do we think lightly of the qualifications that ought to be possessed by every one who practises medicine. We do not think one degree of knowledge good enough for the constitution of the poor, and another for that of the rich; but we do happen to know that the ignorant poor, as well as the ignorant rich, will not go exactly where the best knowledge and skill are to be procured. They will go where they please; and if a totally uneducated man can attract the public to his shop, not only for medicine but for advice, then we would say, that to insist on those who advise having some qualification instead of none, is wise and humane.

The new bill, it seems, proposes to allow those to practise who are already practising, and will insist on the qualifications of future candidates being sufficient to render their practice at least harmless. This seems to be pretty much what was done in the case of the apothecaries. The Apothecaries' Act let in all those who were in practice before 1815; subjected all future candidates for admission to the surveillance of the Worshipful Society: and whatever theoretical objections may be made to appointing a private corporation the guardians of public interest in so important a matter, it is notoriously matter of experience that the present false position of the apothecary is in great degree consequent on the high standard of education required for the license of the Worshipful Society,—a circumstance indicating no neglect, on their part, of the public health.

The principal remedy for the existing evils is to be found in the gradual and persevering exertions of the general practitioner to improve his acquirements and his position, to educate

himself and all about him to the highest standard of real professional dignity that his present position admits of. Let him be paid for his time and skill, not for his physic; and we would add, let him not hold that time and skill too cheap—charge enough for them when they are required, but pay no more visits than are wanted.

The physician and pure surgeon must take care of themselves, to keep their acquirements so much above those of the majority that they shall be looked up to as advisers worth having. This their ample means, the prolonged and scientific studies which they can command, and the public appointments for which these may fit them, ought to enable them to do. If these opportunities do not make them superior, no legislation will do so. Of really consulting physicians or surgeons but few are required, and those few must be really the best.

It would probably not be expedient, as it assuredly is not practicable, for the general practitioner to give up at once the dispensing of his own medicines. The public are not educated up to this; the profession cannot afford it. It is an excellent guarantee for the goodness of the drugs, that they are furnished by a person deeply concerned for their efficiency; only, do not let them be the thing paid for. We have no great faith in public meetings, to do badly and with tumult what the same number of persons could better do quietly, or we could wish there were an association to settle a scale of charges, below which no member should practise under pain of expulsion; but unity, not uniformity—individual firmness, not united clamour, are what the circumstances require.

MEDICAL REFORM.

(HOUSE OF COMMONS, Tuesday, April 25.)

MR. MACAULAY wished to put a question to the right hon. baronet the Secretary of State for the Home Department respecting a very important subject—he meant the subject of reform in the medical profession. He wished to know whether those negotiations which he had been told were in progress some time ago on this subject, had been brought to such a termination as to enable the introduction of a bill into Parliament on the subject? He wished to know, secondly, whether there was any reasonable expectation of such an act being passed into a law this session? And thirdly, if the right hon. baronet felt that they could not expect to pass a general measure on the subject this session, whether he would have any objection to introduce into the Poor Law Act a clause to remedy the most pressing and crying grievances under which the medical profession now laboured, from the construction of the present law, in the exclusion of Scotch and Irish medical men from practising in the workhouses?

Sir J. Graham said, he had no hesitation in saying that the negotiations to which the right hon. gentleman referred had been as far successful as to leave no doubt on his mind that in a very short period he should be able to ask the leave of the house to introduce a measure with respect to the medical profession. As to the second question of the right hon. gentleman, whether there was any hope of passing such measure this year, that of course must depend on the reception given to it. He was disposed to think that the measure was worthy the attention of the house, and he should bring it forward in the expectation that it would pass this session. At the present time he felt certain he should be able, in the course of the present session, to bring forward a measure on the subject, and it was his confident belief that it would pass into a law this session. He should only advert briefly to the third point. He felt that the practitioners of Scotland and Ireland were subjected to great hardship by the interpretation put on the act with reference to English practitioners, and that some legislative measure was called for on that particular point.—*Times*.

WIDOWS AND ORPHANS SOCIETY.

DEATH OF THE DUKE OF SUSSEX,
THE PATRON.

THE late lamented Duke of Sussex became the patron of this Society on the death of the Duke of Kent, in 1820.

As soon as the death of His Royal Highness, on Friday last, was made known, an Extraordinary Court of Directors was summoned, by requisition, to consider the propriety of postponing the Annual Dinner of the Society.

The Dinner had been appointed to take place on Saturday, the 29th instant, and His Royal Highness the Duke of Cambridge had graciously consented to preside on the occasion. The postponement was unanimously resolved on.

No other day can with propriety be fixed until the termination of the Court mourning, when it is probable that the Stewards will again endeavour to obtain the gracious presence of the royal Chairman.

MEDICO-LEGAL EVIDENCE IN A CASE OF SUSPECTED POISONING.

To the Editor of the Medical Gazette.

SIR,

I FORWARD to you an outline of the trial of Mary Hunter, indicted for the murder of her late husband, by administering to him arsenic, which caused the disease of which he languished from the 25th to the 28th of November, and then died. She was also arraigned on the coroner's inquest.

When your readers are informed that this trial, which was brought to a premature close by the case for the prosecution breaking down under the able cross-examination of the witnesses against the prisoner, before anything was urged in her defence, they will at once see that it is alike impossible for you to publish, or for me to write, a full report of the whole case. I will therefore attempt no more than to state, in the most succinct manner I am able, what, to the best of my judgment, are the true facts, qualifying those which were stated in the prosecution by what I know would have been urged in defence. I intend, at the earliest possible opportunity, to prepare a full account, which, in consequence of my very intimate knowledge of the circumstances, I believe I can do more completely than any other individual; if any, therefore, suspect that the following account is a partial one, I entreat them to suspend their judgment until they see the whole.

I will not attempt giving an outline of the evidence of each witness, for that you can refer to the Liverpool newspapers (the Mail and the Albion contain the best reports I have yet seen, but very imperfect nevertheless): I prefer stating in the natural order the circumstances which I consider proved, and which would not have been disproved by the witnesses or arguments for the defence.

Mr. Wilkins and Mr. Mouk appeared for

the prosecution, and Mr. Pollock, of Manchester, for the defence.—I am, sir,

Your obedient servant,

P. H. HOLLAND, M.R.C.S.L.

Manchester, April 10, 1843.

Character of the deceased.—It was clearly proved that the deceased, a mechanic, was a hard-working thrifty man, of steady habits: that he had laid by a considerable amount of money as provision for himself and for his family; that he was a kind husband and father; and those in most immediate connexion with the family believed that for ten years he had lived with the prisoner in peace and comfort.

Character of the prisoner.—The witnesses all agreed in saying that she was an attentive wife and kind mother: that she was remarkable for keeping her husband's house clean and tidy. The only fault ascribed to her was the unhappy practice of drinking. It did not appear that she was a positive drunkard, but certainly she drank much and often. An attempt was made to prove that a long time ago she stole money from her husband to pay her drinking debts, lest he should discover her bad behaviour; and mention was made of some indecent levity of which it was said she had been guilty nearly two years before; committed, however, in the presence of witnesses who themselves considered it a joke. May we not judge of the *animus* with which the prosecution was urged by the fact of these old stories having (even if true) been raked up against her?

Poison in possession of prisoner.—It was distinctly proved, and, though at first denied, afterwards acknowledged by the prisoner, that she had purchased two ounces of arsenic, as she said, to poison twitchclocks (black-beetles) and mice. It was also proved that her next-door neighbour's house, and therefore probably her own, was infested with twitchclocks, and though no mice were found on searching the house, that is no proof they were not there.

An attempt was now made to show that the arsenic was bought *secretly*, but it signally failed. She says that she lost the arsenic on her way home, and a witness said that she had given her the same account a week preceding the deceased's illness; and it is most probable that this is true, for a most diligent search discovered no trace of arsenic in any part of the premises. If so much as two ounces had been put into the fire, its penetrating garlicky fumes would have been almost inevitably perceived; if put into the privy, almost as inevitably detected by the rigorous chemical analysis which was instituted.

Behaviour of the accused.—At the inquest the witnesses all agreed in saying that nothing in her behaviour had excited their

suspicion. When her husband was taken suddenly ill, she quickly gave the alarm, and ran off herself to her usual doctor, and not finding him in went to a second; again failing, went to a third, whom her husband wished to have. She nursed him attentively throughout his illness; told Mr. Harrison, the surgeon, that she was sorry he had not come sooner, as she had expected. This readiness to put the case under medical observation looks very unlike conscious guilt. The only neglect attributed to her was allowing the water to escape from a bottle put to her husband's feet, by which the bed was wet, and was allowed to remain so. There was no hasty putting away of the matters purged or vomited; there was a very natural attempt made to avoid inspection and an inquest, and a hasty seeking to get possession of his property. This, she says, was because she thought his relations would try to prevent her getting it; a suspicion which events have shown was not entirely without foundation.

Previous health of the deceased.—This was stated to have been perfectly good, as he was never off his work from illness, and had made no applications for "sick money" from the club; but I believe that though never positively ill, he was rarely quite well, that he had recently had syphilis, and probably had had mercury, that he had habitually stinking breath, griping pains, uncertain appetite, and wind; for which he was in the habit of taking cayenne pepper.

History of the fatal disorder.—The deceased returned from work about 6 on Friday evening, the 25th of November last, in apparently good health; he took five or six spoonfuls of porridge made with milk and meal, and almost immediately became violently sick, with vomiting and purging. The matter first vomited was large in quantity, frothy brown, and offensive, and appeared to contain pieces of carrot; no particular examination of it was made. He was apparently purged violently; the first stools were not observed; that which the surgeon's assistant saw was clay-coloured and not particularly offensive, but one of the attendants said one before was ragged, loose, of a foul colour, and very bad smell. The deceased became extremely exhausted, and in half an hour was unable to walk, and when he was taken by the arm to be assisted to bed he screamed from pain, probably from the abdomen being thereby stretched.

When taking the porridge he complained of its taste: said, "Mary, thou hast put summut in this porridge, either pepper or snuff:" it made his throat hot and painful. This heat of the throat seems to have been complained of for a very short time only. The accused said that she had that morning boiled some cayenne pepper in the pan in which the

porridge was made, and that perhaps she might have neglected to wash it out. If any thing was in the porridge it must have been something besides arsenic, as that has no taste, would not very quickly produce heat of the throat, which cayenne would, and the heat produced by arsenic would not be, like that produced by a small quantity of cayenne, temporary only. The vomiting and purging having continued violently for half an hour, gradually subsided, and after two or three hours entirely ceased, and did not again recur; the pain and tenderness also, which had been violent at first, were entirely absent afterwards: upon this point the surgeon speaks quite positively: "he had no pain or tenderness at all after the subsidence of the vomiting." This is exceedingly unlike the progress of fatal gastritis from arsenic: there are many fatal cases recorded of no pain having been complained of at all, cases in which the patient dies from the overpowering effect upon the nervous system—one such I have myself put on record in your pages—but has there been one single case of severe pain once excited ever subsiding, except for short intervals, unless, indeed, recovery has followed? I am sure it is extremely rare, if ever it happened at all.

The deceased was seen at 9 o'clock, about three hours after the apparent commencement of the disorder, by Mr. Willis, assistant to Mr. Harrison, who describes his state then as that of collapse—the pulse very weak, and the extremities cold: the stool which he saw was clay-coloured, and the vomiting not bilious. He was then retching violently, but there was no vomiting. Mr. Willis considered it a case of common cholera, and prescribed some calomel and opium, and effervescing draughts with ten minims of laudanum in each.

It is probable that the case was not at that time considered a serious one, for Mr. Harrison did not visit the patient till 3 P.M. the succeeding day, 23 hours after the commencement of the disorder: the wife, however, complained that he did not come before. He found the patient "still in collapse, pulseless, very weak, with difficulty of breathing, no particular pain nor tenderness on pressure, which he had expected after such violent vomiting:" the vomiting and purging had then entirely ceased, and did not recur: he subsequently became costive. He was not in a state of stupor, but indisposed to answer questions. He had no hoarseness or change of voice; no remarkable change of countenance: he looked merely anxious and sharpened. The eyes were a little sunk, but not red or bright, or otherwise remarkable. The questions by which all this was elicited so distinctly and so unequivocally were put by Mr. Pollock in a manner which showed that he was, as I know he is, quite

conversant with the subject, and should be a warning to all members of our profession how they venture unprepared into a witness-box. As I differ from Mr. Harrison in the view which he takes of this case, I think it only just to say that I am sure but very few could have borne so well so stringent an examination; a hundred times more severe and searching than I got at either the College or the Hall, whatever the experience of others may have been. But to proceed with the history. On Sunday forenoon Mr. Harrison found the patient "in the same state;" "he was very restless, had great thirst and tightness across the chest, and suppression of urine." There being yet no reaction, he thought the man in great danger, and told his wife so. He ordered him a drop of prussic acid in the effervescing mixture, a blister to his stomach, a bottle of hot water to his feet, and a mustard bath (to his feet, as I understand). All these means were properly employed, except from the carelessness about the bottle of hot water, which might easily pass undetected without any culpable negligence, as the man was so nearly insensible; and it appeared to me ungenerous in Mr. Wilkins to urge it against the wife as a presumption of animal indifference to her sick husband's comfort and safety.

On Sunday night he was seen again, and remained still in the same state.

On Monday morning he had great thirst, could scarcely speak, and was evidently dying.

One of his fellow workmen is reported to have heard him express, on the Monday, a strong expectation of recovery: "he had been very ill, but would be at his work by the end of the week." I have not, however, verified this statement; I suspect there is some error as to the time at which it was said. He had cramp on the Monday evening, but no convulsions or paralysis. He died on Monday night, about seventy-five hours after taking the suspected article of food.

Though both he and the accused herself attributed his illness to the porridge, he does not appear to have himself entertained any suspicion of her intentions. The wife foolishly, but very naturally, threw away the porridge and basin, and the meal of which it was made, lest, as she said, somebody else should be made ill by them. Some porridge found in a broken basin, in the privy, supposed to be this, was analysed, and nothing found. The deceased told his wife that the porridge was not fit to eat, and she might give it to the dog. She replied, "nay, if it has hurt you it will hurt him, she would throw it away;" and who is there that loves a dog that would not have done just the same? Though these little circumstances have been dwelt upon after-

wards as presumptions of guilty knowledge, so little did this attract notice at the time that no suspicion whatever appears to have been excited, until it was learned, the day after the man's death, that the wife had purchased arsenic from the druggist who was accustomed to supply her with medicine, who she herself voluntarily told that her husband was sick to death, and that Mr. Harrison was attending him—a very extraordinary communication to make by a woman who had a guilty knowledge of *the cause* of that sick husband's illness! Suspicion, however, being thus excited, a coroner's inquest was summoned, and an inspection of the body ordered, which was made on Tuesday evening, by Mr. Harrison and Mr. Dyson, Surgeons.

Externally every thing appeared healthy. There was no blackness or lividity of the genitals; no eruption of any kind; the body was not at all supple, as it often is when blood is prevented from coagulating by arsenic. The *post-mortem* contraction of the muscles seems to be, like the coagulation of the blood, the last act of vitality, and appears to be prevented by the same circumstances, namely a rapid exhaustion of the vital powers before death.

On opening the cavity of the abdomen every thing appeared healthy, till, on "removing the stomach and intestines as far as the rectum, and laying them open, very considerable inflammation presented itself in the stomach in particular, and in patches throughout the intestinal canal to the rectum, where there was considerable irritation; patches of redness in the jejunum; great corrugation of the bladder." The stomach and bowels were found *empty*, except a piece of potatoe at the pylorus (it appears that the deceased had not eaten potatoes during his illness; the last time was on Friday at noon). Upon more particular inquiry Mr. Harrison said that there were about four ounces of reddish brown fluid, apparently coloured with blood, in the alimentary canal, which is consistent enough with the expression *empty*; whereas Mr. Dyson's account, that "there was a large quantity of bloody fluid," is not consistent with Mr. Harrison's and his own previous description.

The mucous coat was highly inflamed in distinct patches, with evident destruction of some portions of that membrane. The patches were brick red, rather than black or brown, in colour; did not look as if they were seared with a hot iron. Mr. Harrison is doubtful if there was any real ulceration, or any thing more than abrasion with softening. Mr. Dyson speaks positively to ulceration. I believe neither of these practitioners pretend to any great accuracy of knowledge in morbid anatomy; and we shall all acknowledge this is a point not always easy to determine. Mr.

Harrison said positively that there were no livid spots on the mucous membrane; Mr. Dyer says that there were spots of extravasated blood on various parts of the mucous membrane. These appearances were not mentioned at all by the examiners in their written report the day after the examination, and it is difficult to believe that so remarkable a circumstance could have been overlooked even by the most careless observer, which we have no reason for supposing Mr. Harrison to be.

Both of the surgeons state that, in their opinion, the appearances are strongly indicative of irritant poisoning. Mr. Harrison stated, with some natural hesitation, that he thinks no natural disease with these symptoms would produce them. Mr. Dyson rests his opinion, which he gave in the most confident manner, upon his assertion that there was "intense inflammation of the mucous membrane of the stomach and bowels; very great degree of softening of the same membrane; spots of extravasated blood on various parts; a great number of points of ulceration, which were most present in those parts of the intestines (the jejunum) which in natural disease are free; and the quantity of red sanguineous effusion throughout the stomach and bowels. That he had been engaged in six cases of poisoning by arsenic; that the appearances in this were similar to those, only more extensive and severe. That the rectum was much inflamed, and also the whole of the large intestines were inflamed; which, Mr. Dyson says, rarely if ever occurs in any natural disease. "The bladder was empty and firmly contracted, which is usual after arsenic;" and after any severe irritation of the pelvic viscera, ought to have been added.

Ulceration of the jejunum, which Mr. Dyson principally relied on for the proof of arsenic, is not frequent after either natural gastro-enteritis, or that from poison, but rather less frequent after the former than the latter. The extent of the inflammation, granting it to have been *real* inflammation, of which there may be not unreasonable doubts, is, so far as it goes, a presumption against, rather than for, the supposition of poisoning.

But the strongest point is still to come. The stomach and the bowels, with their contents, were given to Mr. Davies, an experienced and careful chemist, who made an elaborate analysis of the tissues, as well as of the contents of the alimentary canal, and discovered nothing. Now, no one will assert that arsenic may not have done all this mischief, and have been entirely discharged by two or three hours' vomiting and purging; but has one such case ever occurred? I cannot find one. The only one approaching to it is mentioned by Dr. Christison, and in that he discovered the

25th of a grain. My friend, Professor Montagu Phillips, and I, discovered and verified, from an organic mixture, the one-thousandth of a grain, and procured by Marsh's process unequivocal traces from quantities far smaller. In this case, also, a piece of potatoe was not dislodged: does any one believe arsenic to be as easily dislodged as potatoe? But the arsenic, it has been urged, might have been all in solution; it was stated on oath, positively stated too, that five spoonfuls of milk would dissolve the whole of thirty grains. Mr. Phillips found, by experiment, that two ounces would dissolve half a grain; would half a grain produce this extensive inflammation? It was then urged that more was taken, and might have been removed by absorption. But where had it gone? Off by urine? But he had suppression of urine. By perspiration? His skin was dry. By pulmonary perspiration? Does arsenic volatilize at a blood heat? It was carried to the other parts of the body. Where is the evidence of any considerable quantity being so carried?

I think I need not trespass further upon your space: I hope, if any of your correspondents know of cases in which any of these unusual circumstances have happened, they will point out where they are recorded.

I am, sir,
Your obedient servant,
P. H. HOLLAND.

NON-MALIGNANT MAMMARY TUMOR OF FOUR YEARS' STANDING—EXTIRPATION —CURE.

ELLEN CURTIS, *ætat.* 23, unmarried, from Gloucester county, New Jersey, was admitted February 17th, on account of a large tumor of the right breast. She states that some time in the winter of 1838, she first perceived a small, moveable tumor, situated apparently just below the skin, and on the inner side of the right mamma. This gave but little uneasiness, till it increased to the size of a walnut, when she received a kick on the part from a cow, after which it was at times slightly painful. She now covered it with a simple plaster, which treatment was continued till the month of May 1841, when she fell into the hands of a quack, who applied a caustic plaster to the part—the course of a short period of 14— a lancet into the tumor 12— twelve different times— no discharge followed— application of the 3 sloughing of the skin left an ulcerated 27

up to the present period. After this treatment the tumor slightly enlarged, and has since that time presented a more angry and inflamed appearance. Five weeks since, owing to a large venous trunk having been opened by extension of the ulceration, hemorrhage to a very large amount took place, which was arrested upon the occurrence of syncope ; and on the evening previous to her admission into the hospital a second bleeding to the extent of three pints had occurred, from the same cause, which was arrested by pressure.

The tumor is now of large size, is very heavy, and is observed to be strongly lobulated, deep depressions existing between the lobes. These lobes are hard and inelastic, and the whole tumor is loose and free from any attachment to the parts beneath. About one-fourth of the skin covering the breast is ulcerated, the parts below presenting the appearance of a healthy indolent ulcer, discharging laudable pus, and with nothing like a fungous growth protruding from it. No hemorrhage has ever occurred from the surface of the ulcer. The skin is reddened around the ulcerated part, but is at no point puckered, and the veins on the upper surface of the breast passing towards the neck are very much enlarged. The nipple is observable, below the ulceration, healthy in structure, though nearly obliterated ; at no time has there been any discharge from it. The tumor is not tender to the touch, neither is it painful, except on the approach, and during the continuance, of the menstrual discharge ; and with the exception of its weight and size, the patient, until within a short time, has experienced no inconvenience from it, and up to within two weeks of her admission into the hospital had been actively employed in the domestic duties of a farmer's family. The left breast is of normal size and appearance. Her general health is good, and there is no enlargement of the cervical glands, or of those in the axilla. She is not emaciated, and her skin is free from sallowness, though her appearance is that of a person debilitated from large losses of blood. Her menstrual periods, which on the first appearance of the swelling were irregular, both as to quantity and time, are now natural, and with the exception of some enlargement of the tonsils, she presents no mark of a scrofulous taint.

Upon the first aspect of this case it presented the appearance of, and might upon a superficial examination have been pronounced, a tumor of a malignant kind ; but the history of its rise and progress, as well as a careful examination of it, readily showed its true nature. The age of the patient, the want of sallowness in her skin, her comparatively good general health, and the slight pain she had suffered from it, were alone sufficient to lead us to suspect its freedom

from malignancy ; and when taken in connection with the great weight of the tumor, its loose attachment to the surrounding parts, the slow progress and duration of the disease, the absence of glandular disease in its vicinity, together with the want of all fungous growth, and the discharge of laudable pus from its ulcerated surface, and its marked lobulated feel and appearance, proved conclusively that the character of this case had nothing in common with either cancer or fungus hæmatodes. The disease was looked upon as belonging to that class denominated chronic mammary tumors, and in the advanced stage in which it existed, evidently a proper case for the knife. It differed, however, from most tumors of this class in its great size, and a correct diagnosis of it was particularly important, as we could confidently predict for the sufferer freedom from any return after the operation.

In consequence of the occurrence of her menstrual period a day or two after her admission into the hospital, the disease was not extirpated till the 2d of March. The operation was done in the usual manner, the tumor being included in two elliptical incisions. The hemorrhage following it was not great ; a point of suture was inserted in the middle of the wound, and its sides, in addition, were brought together with two or three strips of adhesive plaster, after which the wound was covered with a little lint, and the arm supported by a sling.

Upon examination after removal, the tumor was found to be made up of a number of separate lobes, very closely connected together by cellular tissue. The structure of these lobes was very dense, and when divided presented very much the appearance of sweetbread. No vessels could be traced running through the tumor, which was completely surrounded by a covering of thick tendinous substance.

After the operation, she suffered from repeated attacks of erysipelas, as well around the wound as on the back, abdomen, legs, arms, and face. These were treated by a careful use of the blue pill and mild cathartics, together with neutral or effervescing mixtures ; the parts affected being bathed with soap liniment ; and in consequence of her great debility, tonics and nourishing food of an unstimulating kind, in such forms and quantities as her excessively irritable stomach would allow her to retain, were administered. The applications to the wound, after the first day or two, were principally the common mucilaginous or water dressing, an adhesive strap being at the same time applied, to favour cicatrization.

On the 25th of March a large abscess seated over the lower part of the back was opened. On the 31st, abscesses which had formed on both upper extremities above the

elbows, were opened. By the 2d of April, the wound was completely cicatrized. On the 12th and 23d of April, other large collections of matter, resulting, as in the former instances, from erysipelas, were laid open, and on the 5th of May she left the hospital for Jersey, in good health.—*American Journal*.

MATERIA MEDICA.

MR. BATTLE requests us to announce that he has re-opened his Museum of Materia Medica at the Saunderian Institution, adjoining the Ophthalmic Hospital, Moorfields, and that he will also exhibit on a larger scale the articles of the Materia Medica, classed according to their operation on the human body.

The latter articles will be demonstrated and described on the second Friday of each month.

The class "Purgatives," now ready for inspection, and will be described on Friday, May 12th, at 4 P.M.

DECEASE OF DR. LATHAM.

"On the 20th instant, at Bradwall Hall, Cheshire, in his 82d year, John Latham, M.D. F.R.S., formerly President of the Royal College of Physicians."

The preceding notice is copied from the newspapers; and we may add, that Dr. Latham was for many years a highly respected practitioner in London, but had latterly resided entirely at his place in Cheshire.

LITERARY INTELLIGENCE.

MR. CHURCHILL will shortly publish the following Works:—

Dr. Prout, F.R.S.—On the Nature and Treatment of Stomach and Urinary Diseases. Fourth edition, with considerable additions.

Dr. Williams, F.R.S.—Principles of Medicine: comprehending General Pathology and Therapeutics.

Dr. Royle, F.R.S.—A Manual of Materia Medica, illustrated with wood engravings.

G. J. Guthrie, F.R.S.—On the Anatomy and Diseases of the Urinary and Sexual Organs. Third edition.

A. Taylor, F.L.S.—A Manual of Medical Jurisprudence.

G. Fownes, Ph.D.—A Manual of Chemistry.

Dr. Golding Bird, F.L.S.—Elements of Natural Philosophy. Second edition, with considerable additions.

Dr. Hall, F.L.S.—Clinical Remarks on Diseases of the Eye, and on Miscellaneous Subjects, Medical and Surgical.

J. Yearsley.—On the Enlarged Tonsil

and Elongated Uvula, and other Morbid Conditions of the Throat. Second edition, with additions.

ROYAL COLLEGE OF SURGEONS.

LIST OF GENTLEMEN ADMITTED MEMBERS.

Friday, April 21, 1843.

C. E. Hatherly. — F. Manning. — G. P. H. Milsons. — A. W. Gabb. — S. Curtis. — R. H. Bradley. — J. Williams. — T. Pollard. — E. Dewes. — W. Pollard. — W. Millington. — C. Scaife. — T. Slater.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, April 20, 1843.

G. Taylor, Derby. — G. Dimock, Sussex. — S. Fenwick, Newcastle. — T. Young, South Shields. — E. J. Newcomb, Kidderminster. — H. H. Parrot, Yorkshire. — R. A. Lafargue. — R. Whitfield, Biddenden.

A TABLE OF MORTALITY FOR THE METROPOLIS,

Shewing the number of deaths from all causes registered in the week ending Saturday, April 15, 1843.

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

By ROBERT LEE, M.D. F.R.S.

LECTURE XXV.

ON PROTRACTED AND DIFFICULT
LABOURS.

6. *Original smallness of the pelvis, distortion, exostoses, and other morbid conditions, are the most frequent causes of difficult labour.*

ABOUT one-sixth of all the cases of difficult parturition which I have observed in London depended upon narrowness of the pelvis, from arrest of development, and distortion. When the pelvis does not expand in the usual manner at the age of maturity, the brim, cavity, and outlet, remain through life smaller than in the ordinary standard female pelvis, without being distorted. In some persons there is no distortion, yet the distance between the base of the sacrum and the symphysis pubis does not exceed three inches, so that a foetal head of the ordinary size cannot pass through it; and all the consequences follow, in labour, which usually take place when a disproportion exists, from distortion or any other cause, between the dimensions of the pelvis and the head of the child. This original smallness of the pelvis exists in a considerable number of women, whose spinal column and long cylindrical bones are not unusually bent, and in whom there is no appearance of rickets, or symptom to excite a suspicion, before the commencement of labour, that the capacity of the pelvis is defective. The effects produced upon the pelvis by softening of the bones from rickets and malacosteon, you have

already seen in a variety of specimens of distorted pelvis, removed from the bodies of women who had died in consequence of the effects produced upon the soft parts from obstruction to the progress of the head of the child during labour.

In small or slightly distorted pelvises, where the short diameters of the brim and outlet exceed three inches, and the long bones of the extremities are not bent, when labour comes on the os uteri dilates in the usual manner, and the head enters the brim, but it passes through with great difficulty. The parietal bones overlap one another, even in the intervals of the pains, and, if the labour is much protracted, a large swelling gradually forms under the scalp, and for hours it may be doubtful whether the uterine contractions will be sufficiently powerful to force the head into the cavity of the pelvis. When it has cleared the brim, if the outlet of the pelvis be less contracted, a few pains only may be required to complete the labour, and the child may be born alive without having sustained any injury. But when the contraction of the brim is greater, the head, after entering more or less deeply into it, ceases to advance, and becomes gradually more and more firmly compressed between the base of the sacrum and symphysis pubis, and at last so completely impacted, locked, or, as it has been expressively called, nailed in the pelvis, that the finger cannot be passed up around the head, and the pains, however violent, have no effect in moving it forward. This state has been termed enclavement or paragonphosis of the head, by foreign writers, and if it is allowed to continue many hours, and the uterus is acting powerfully, the most injurious consequences usually follow both to the child and the mother. In *this* foetal head which I now shew you, the right parietal bone which was applied to the projecting base of the sacrum in labour has been depressed and fractured. Slighter compression of the head, long continued, usually destroys the life of the child before

the labour is finished. If it is born alive death soon afterwards takes place from extravasation of blood upon the brain, producing apoplexy and convulsions.

The soft parts of the mother surrounding the head become hot, dry, tumid, and inflamed, and all the injurious effects of pressure and interrupted circulation of the blood are sooner or later experienced. You cannot pass up the finger around the head without difficulty, and causing more or less distress to the patient; the discharges from the vagina become acrid and offensive; retention of urine takes place, from the pressure of the head on the neck of the bladder and urethra; the abdomen becomes tender; the tongue loaded with urgent thirst; the pulse rapid and feeble; and more or less general exhaustion ensues. In some cases rupture of the uterus takes place in the course of a few hours after the head has become wedged in the brim of a slightly distorted pelvis. Not unfrequently death follows artificial delivery in no long time, when the head of the child has been allowed to remain too long impacted in the pelvis, and still oftener sloughing of the vagina, bladder, and rectum, takes place.

In cases of slighter distortion of the pelvis, it is impossible to predict at the commencement of labour whether the head will pass or not, and while it continues to advance, and no unfavourable symptoms are present, you ought not to interfere—wait patiently, and see what nature can do. If the head descends so low into the cavity of the pelvis that an ear can be felt, and the os uteri is fully dilated, and there is room to pass up the blades of the forceps without the employment of much force, it is always proper, when delivery becomes necessary, to attempt to extract the head with the forceps. It is necessary, however, to remember that sloughing is apt to follow the use of the forceps, where the soft parts have been long pressed upon by the head, and that perforation of the head is a much safer operation for the mother, when the distortion is considerable.

The employment of the long forceps, in cases of distorted pelvis, has been recommended by Baudelocque, Boivin, Lachapelle, Capuron, Maygrier, Velpeau, and Flammant, whose works contain ample instructions for its use, before the head of the child has entered the brim of the pelvis; and the last of these writers has expressed his belief that the instrument is more frequently required while the head of the child remains above the superior aperture of the pelvis, than after it has descended into the cavity.

In this country there are no practitioners of judgment and experience who have frequent recourse to the forceps, or who employ it before the orifice of the uterus is fully dilated, and the head of the child has de-

scended so low into the pelvis that an ear can be felt, and the relative position of the head to the pelvis accurately ascertained. The instrument is very seldom used in England where the pelvis is much distorted, or where the soft parts are in a rigid and swollen state, but it is had recourse to where delivery becomes necessary in consequence of exhaustion, hæmorrhage, convulsions, and other accidents which endanger the life of the mother. It is used solely with the view of supplying that power which the uterus does not possess.

Where the pelvis is distorted in a high degree, as in some of the specimens before you on the table, where the distance from the base of the sacrum to the symphysis pubis varies from an inch and a half to two inches and a half, the head of a full-grown child cannot enter the brim, however long the labour may be allowed to continue. The membranes burst, and the liquor amnii escapes as in natural labour, and the uterus closely contracts around the body of the child, and acts powerfully upon it, but the head presses upon the uterus at a distance from the orifice, and it is never completely dilated. In some cases, where the labour has lasted from forty-eight to sixty hours, the os uteri has not been more than half dilated, and the whole head of the child, swollen by the pressure, has remained entirely within the uterus above the brim, and pushed forward by the base of the sacrum over the symphysis pubis. This figure from Smellie's twenty-eighth table gives a side view of a distorted pelvis, with the head of a full-grown foetus squeezed into the brim, the parietal bones decussating each other, and compressed into a conical form. "This table shows," says Smellie, "the impossibility, in such a case, to save the child unless by the Cæsarean operation, which ought, however, never to be performed, excepting when it is impracticable to deliver at all by any other method. Even in this case, after the upper part of the head is diminished in bulk, and the bones are extracted, the greatest force must be applied, in order to extract the bones of the foetus and basis of the skull, as well as the body of the foetus." (See top of next page.)

The following figure from Smellie's twenty-second table gives a lateral view of a distorted pelvis, divided longitudinally, with the head of a foetus of the seventh month passing the same. "The head of the foetus here," he says, "though small, is with difficulty squeezed down into the pelvis, and changed from a round to an oblong form before it can pass, there being only the space of two inches and a quarter between the projection of the superior part of the sacrum and os pubis. If the head is soon deli-

vered the child may be born alive; but if it continues in this manner many hours, it is in danger of being lost, on account of the long pressure on the brain; to prevent which, if the labour-pains are not sufficiently strong, the head may be helped along with the forceps." "This figure may serve as an example of the extreme degree of distortion of the pelvis, between which and the well-formed one are many intermediate degrees, according to which the difficulty of delivery must increase or diminish, as well from the disproportion of the pelvis and head of the foetus—all which cases require the greatest caution, both as to the safety and management of the mother and child."

Where there exists a great degree of distortion of the brim of the pelvis, you may be unable to determine positively the distance between the base of the sacrum and symphysis pubis; and it is not necessary for practical purposes to do so with mathematical accuracy; but when it is under two inches and a half, you will readily discover,

if you have had considerable experience, on making the ordinary examination, from the unusual manner in which the sacrum projects, that it is impossible for a child at the full period to pass through it. If labour has commenced at the full period of pregnancy, and you discover before it has continued many hours that the pelvis is greatly distorted, and that the child cannot possibly pass alive, no advantage can result from allowing the labour to endure till the patient is exhausted, and you are satisfied that the difficulty cannot be overcome by the powers of the constitution. In such a case delay is dangerous, and there is nothing which can save the woman's life but opening the head of the child with the perforator, and extracting it with the crotchet. But this should never be had recourse to without a regular consultation of experienced practitioners, and before it has been placed beyond all doubt, by the most careful investigation, that the delivery can be accomplished in no other manner so as to preserve the mother's life.

In the greater number of cases of difficult labour from a high degree of distortion of the pelvis which have come under my observation, where it has been the first child, the process has been allowed to go on till the efforts of the patient were nearly discontinued, or had ceased entirely, and the favourable period for operating was lost. In some cases, even when the duration of the labour, and the local and constitutional symptoms, have made it manifest that such interference was justifiable and necessary, I have unfortunately delayed too long to deliver, in consequence of employing the stethoscope, and ascertaining that the child was alive. In cases of extreme distortion of the brim of the pelvis the proper practice is to perforate the head, as soon as the os uteri is sufficiently dilated to admit of the operation being done with safety, and afterwards leaving the patient in labour till the head has partially entered the brim, and the os uteri is considerably dilated. There can be no doubt that, in some cases, it is right to interfere before we certainly know that the child has been destroyed by the pressure; but we have nothing here to do with the question respecting the life or death of the child; our conduct will be biased if we endeavour to solve this question. We have only to determine positively that delivery is absolutely necessary to save the mother's life, and that it is impossible for the head of the child to pass till its volume is reduced. Paré, Guillemeau, Mauriceau, Portal, Puzos, Levret, Smellie, and all the best accoucheurs who have since appeared in Britain, have performed the operation of craniotomy in many cases of distortion from rickets and malacosteon,

the labour is finished. If it is born alive death soon afterwards takes place from extravasation of blood upon the brain, producing apoplexy and convulsions.

The soft parts of the mother surrounding the head become hot, dry, tumid, and inflamed, and all the injurious effects of pressure and interrupted circulation of the blood are sooner or later experienced. You cannot pass up the finger around the head without difficulty, and causing more or less distress to the patient; the discharges from the vagina become acrid and offensive; retention of urine takes place, from the pressure of the head on the neck of the bladder and urethra; the abdomen becomes tender; the tongue loaded with urgent thirst; the pulse rapid and feeble; and more or less general exhaustion ensues. In some cases rupture of the uterus takes place in the course of a few hours after the head has become wedged in the brim of a slightly distorted pelvis. Not unfrequently death follows artificial delivery in no long time, when the head of the child has been allowed to remain too long impacted in the pelvis, and still oftener sloughing of the vagina, bladder, and rectum, takes place.

In cases of slighter distortion of the pelvis, it is impossible to predict at the commencement of labour whether the head will pass or not, and while it continues to advance, and no unfavourable symptoms are present, you ought not to interfere—wait patiently, and see what nature can do. If the head descends so low into the cavity of the pelvis that an ear can be felt, and the os uteri is fully dilated, and there is room to pass up the blades of the forceps without the employment of much force, it is always proper, when delivery becomes necessary, to attempt to extract the head with the forceps. It is necessary, however, to remember that sloughing is apt to follow the use of the forceps, where the soft parts have been long pressed upon by the head, and that perforation of the head is a much safer operation for the mother, when the distortion is considerable.

The employment of the long forceps, in cases of distorted pelvis, has been recommended by Baudelocque, Boivin, Lachapelle, Capuron, Maygrier, Velpeau, and Flaminant, whose works contain ample instructions for its use, before the head of the child has entered the brim of the pelvis; and the last of these writers has expressed his belief that the instrument is more frequently required while the head of the child remains above the superior aperture of the pelvis, than after it has descended into the cavity.

In this country there are no practitioners of judgment and experience who have frequent recourse to the forceps, or who employ it before the orifice of the uterus is fully dilated, and the head of the child has de-

scended so low into the pelvis that an ear can be felt, and the relative position of the head to the pelvis accurately ascertained. The instrument is very seldom used in England where the pelvis is much distorted, or where the soft parts are in a rigid and swollen state, but it is had recourse to where delivery becomes necessary in consequence of exhaustion, hæmorrhage, convulsions, and other accidents which endanger the life of the mother. It is used solely with the view of supplying that power which the uterus does not possess.

Where the pelvis is distorted in a high degree, as in some of the specimens before you on the table, where the distance from the base of the sacrum to the symphysis pubis varies from an inch and a half to two inches and a half, the head of a full-grown child cannot enter the brim, however long the labour may be allowed to continue. The membranes burst, and the liquor amnii escapes as in natural labour, and the uterus closely contracts around the body of the child, and acts powerfully upon it, but the head presses upon the uterus at a distance from the orifice, and it is never completely dilated. In some cases, where the labour has lasted from forty-eight to sixty hours, the os uteri has not been more than half dilated, and the whole head of the child, swollen by the pressure, has remained entirely within the uterus above the brim, and pushed forward by the base of the sacrum over the symphysis pubis. This figure from Smellie's twenty-eighth table gives a side view of a distorted pelvis, with the head of a full-grown foetus squeezed into the brim, the parietal bones decussating each other, and compressed into a conical form. "This table shows," says Smellie, "the impossibility, in such a case, to save the child unless by the Cæsarean operation, which ought, however, never to be performed, excepting when it is impracticable to deliver at all by any other method. Even in this case, after the upper part of the head is diminished in bulk, and the bones are extracted, the greatest force must be applied, in order to extract the bones of the foetus and basis of the skull, as well as the body of the foetus." (See top of next page.)

The following figure from Smellie's twenty-second table gives a lateral view of a distorted pelvis, divided longitudinally, with the head of a foetus of the seventh month passing the same. "The head of the foetus here," he says, "though small, is with difficulty squeezed down into the pelvis, and changed from a round to an oblong form before it can pass, there being only the space of two inches and a quarter between the projection of the superior part of the sacrum and os pubis. If the head is soon deli-

vered the child may be born alive; but if it continues in this manner many hours, it is in danger of being lost, on account of the long pressure on the brain; to prevent which, if the labour-pains are not sufficiently strong, the head may be helped along with the forceps." "This figure may serve as an example of the extreme degree of distortion of the pelvis, between which and the well-formed one are many intermediate degrees, according to which the difficulty of delivery must increase or diminish, as well from the disproportion of the pelvis and head of the fœtus—all which cases require the greatest caution, both as to the safety and management of the mother and child."

Where there exists a great degree of distortion of the brim of the pelvis, you may be unable to determine positively the distance between the base of the sacrum and symphysis pubis; and it is not necessary for practical purposes to do so with mathematical accuracy; but when it is under two inches and a half, you will readily discover,

if you have had considerable experience, on making the ordinary examination, from the unusual manner in which the sacrum projects, that it is impossible for a child at the full period to pass through it. If labour has commenced at the full period of pregnancy, and you discover before it has continued many hours that the pelvis is greatly distorted, and that the child cannot possibly pass alive, no advantage can result from allowing the labour to endure till the patient is exhausted, and you are satisfied that the difficulty cannot be overcome by the powers of the constitution. In such a case delay is dangerous, and there is nothing which can save the woman's life but opening the head of the child with the perforator, and extracting it with the crotchet. But this should never be had recourse to without a regular consultation of experienced practitioners, and before it has been placed beyond all doubt, by the most careful investigation, that the delivery can be accomplished in no other manner so as to preserve the mother's life.

In the greater number of cases of difficult labour from a high degree of distortion of the pelvis which have come under my observation, where it has been the first child, the process has been allowed to go on till the efforts of the patient were nearly discontinued, or had ceased entirely, and the favourable period for operating was lost. In some cases, even when the duration of the labour, and the local and constitutional symptoms, have made it manifest that such interference was justifiable and necessary, I have unfortunately delayed too long to deliver, in consequence of employing the stethoscope, and ascertaining that the child was alive. In cases of extreme distortion of the brim of the pelvis the proper practice is to perforate the head, as soon as the os uteri is sufficiently dilated to admit of the operation being done with safety, and afterwards leaving the patient in labour till the head has partially entered the brim, and the os uteri is considerably dilated. There can be no doubt that, in some cases, it is right to interfere before we certainly know that the child has been destroyed by the pressure; but we have nothing here to do with the question respecting the life or death of the child; our conduct will be biassed if we endeavour to solve this question. We have only to determine positively that delivery is absolutely necessary to save the mother's life, and that it is impossible for the head of the child to pass till its volume is reduced. Paré, Guillemeau, Mauriceau, Portal, Puzos, Levret, Smellie, and all the best accoucheurs who have since appeared in Britain, have performed the operation of craniotomy in many cases of distortion from rickets and malacosteon,

striking in the following case:—On Jan. 23, 1842, Mr. Kell, of Bridge Street, Westminster, requested me to see, with him and Dr. Hingeston, a woman, æt. 28, who was in the seventh month of her first pregnancy, and whose pelvis was greatly distorted by rickets. Some days before, Dr. Hingeston had passed a sound into the uterus, and detached the membranes from the lower part, but labour did not take place. I found the os uteri high up, and situated close behind the symphysis pubis. No difficulty was experienced in perforating the membranes in the usual manner, and the liquor amnii afterwards began to escape, and continued to flow till the evening of the 26th, when strong labour pains commenced. At 6 a.m. on the 27th, the os uteri was considerably dilated, and the nates were felt presenting. As it was obvious the breech would never pass through the brim, I brought down the lower extremities with the blunt end of the crotchet, and extracted the trunk without difficulty; but I was obliged also to bring down the arms with the blunt hook. Afterwards I endeavoured to pass up the perforator to the back part of the head, and open it, but could not succeed in getting the point of the instrument beyond the upper cervical vertebrae. Being afraid of separating these, and detaching the head from the trunk, I gave up the attempt to perforate the back part of the head, and tried to draw the head through the brim of the pelvis with the crotchet, by fixing the point of the instrument over the bones of the face and forehead. After much exertion, continued for nearly two hours, the head was at last extracted, when completely torn to pieces. I believe it would have been impossible, in this case, to perforate the skull through the roof of the mouth, as has sometimes been done where similar difficulties have presented to perforating the back part of the head. The placenta was soon expelled, and the patient had a perfect and rapid recovery. It is impossible to doubt that the result of this case would have been widely different had the patient been allowed to go on without interference till the end of the ninth month. Being certain that a child of seven months could not pass through the brim of this pelvis, I resolved to induce premature labour at an earlier period, if

consulted in her subsequent pregnancy. On February 7, 1843, Mr. Kell again requested me to see this patient, who had completed her fifth month of gestation. The stiletted catheter was passed up readily into the uterus, but the liquor amnii did not escape. On the 10th, the point of the stilette having been sharpened, the instrument was again introduced, and the membranes readily punctured. The liquor amnii continued to flow till the 12th, when pains came on, and the child was expelled in a few hours, without artificial assistance. The head presented. The recovery was favourable. I was formerly of opinion that in no case of distortion, however great, could it be necessary to induce premature labour before the end of the fifth month of pregnancy, but in cases of extreme distortion from malacosteon, where the sacro-pubic diameter does not exceed an inch and a half, as in *this pelvis* which you now see, I think it would be advisable to put a period to the pregnancy before the fifth month, which can be done with perfect safety to the mother. The woman from whom *this distorted pelvis* was removed perished in consequence of the membranes not having been perforated sufficiently early. The following figure represents the appearance of a distorted pelvis in the possession of Mr. Barlow, and of the pelvis you now see.

Ritgen has given a table of the period of pregnancy at which labour should be induced, according to the degree of narrowing of the sacro-pubic diameter. Labour, he thinks, should be induced at the twenty-ninth week, when the diameter of the pelvis is two inches and seven lines; in the thirtieth week, when it is two inches and eight lines; in the thirty-first, when it is two inches and nine lines; in the thirty-fifth, when two inches and ten lines; in the thirty-sixth, when two inches and eleven lines; and in the thirty-seventh, when the sacro-pubic diameter is exactly three inches. When it is above three inches, the case must be left to nature.

Mr. Barlow has also published a synoptical table. In a well-formed pelvis, where the distance from the upper edge of the symphysis pubis to the superior part of the os sacrum, or conjugate diameter of the pelvis, is from five to four inches, delivery will take place, he says, by the efforts of nature alone

where the conjugate diameter is from four or four to three or two inches and three quarters, the delivery may be completed by the efforts of nature, or assisted with the forceps or lever ; where from two and three quarters to two and a half inches, premature labour should be induced ; where from two and a half to one and a half inches, by embryulcia, or delivery with the crotchet ; and where the conjugate diameter of the brim is from one and a half inches to the lowest possible degree of distortion, by the Cæsarean operation.

Mr. Barlow thinks this table will facilitate further inquiry, although he justly observes that the practitioner should bear in mind the absolute impossibility of determining the mean degree of compressibility which the cranium of the foetus may undergo by the efforts of the uterus ; and he very properly points out the necessity of making a very careful examination in each case before adopting any decided plan of treatment.

Baudelocque regarded the induction of premature labour as a useless, if not an injurious, operation ; and M. Dugès has recently characterised it as fatal to the mother, and the source of most frightful abuse. In the tables of the Maternité, by Baudelocque, Boivin, and Lachapelle, including nearly 60,000 cases of labour, there is no account of any case in which premature labour was induced. The last of these writers begins her strictures on the practice by declaring that she had never either employed "that method, or seen others have recourse to it." The propriety of inducing premature labour was brought under the consideration of the Academy of Medicine, Paris, in 1827, and they decided that the practice was unjustifiable under any circumstances.

The discordance which exists between Continental and British practitioners is also strikingly displayed respecting the Cæsarean section. The reports of 258 cases of this operation have been collected by Michaelis, 144 of which occurred in the last, and 110 in the present century. Of these cases, 140

proved fatal. Velpeau states that the operation was performed twenty-eight times between 1810 and 1820 ; and thirty-one times from 1821 to 1830. Dr. Churchill says the operation was performed 316 times between 1750 and 1841, and that the mortality was 52·8 per cent. for the mothers. I believe that it would have been much greater if all the unfortunate cases had been published, which has not been done. In Great Britain the reports of at least 27 cases have been published, and in 25 of them it was fatal to the mother. Other fatal cases have occurred which have not been recorded. I believe there is no practitioner of reputation now in this country who would recommend the operation upon the living body if delivery could be effected by the perforator and crotchet. Wherever the presenting part can be reached, to apply the perforator and crotchet, an attempt should always be made to deliver, and the Cæsarean operation reserved for those cases in which the distortion is so great that the os uteri and presenting part are entirely beyond our reach.

Most of you have already examined the following table, which has been published in the first of these clinical reports, exhibiting a comparative view of the frequency of forceps and craniotomy cases in some of the principal lying-in hospitals in Europe. It may be useful once more to compare the practice of different institutions, that you may be convinced that the first principles of operative midwifery have not yet been established, at least that they are not generally understood, and that there is no other branch of surgery at the present time in such a rude condition. In one hospital the forceps was employed once in every seven cases, and in another once only in 728 cases. How important it is that you should watch the progress of protracted and difficult labours, and discover the best method of treatment, and form correct opinions on the use of instruments, it is not necessary for me now to point out to you more particularly.

Hospitals.	Number of labours.	Forceps cases.	Proportion.	Craniotomy cases.	Proportion.

Only a few cases have been recorded in which *Exostoses*, or *Osteo-sarcomatous Tumors of the pelvis*, have produced difficult

labour, and I have not met with any instance in practice.

Dr. M'Kibbin has related an example in

the Edin. Med. and Surg. Journal, April 1831, where the hollow of the sacrum and right side of the brim of the pelvis were occupied by an exostosis of a conical form. The woman had been in labour 50 hours, and the greatest space afforded for the passage of the child was on the right side, and it was only $1\frac{1}{2}$ or $1\frac{3}{4}$ of an inch. From the apex of the tumor to the lower part of the symphysis pubis $1\frac{1}{2}$ inch; from the brim of the pelvis on the right side, immediately over the foramen thyroideum to the lateral surface of the tumor at its widest part, $1\frac{1}{2}$ inch; more posteriorly $1\frac{1}{2}$ inch. The delivery was completed by the Cæsarean operation, but the child was dead, and the woman died after, the unsuccessful result being attributed to the delay. Dr. M. advocates the early adoption of the Cæsarean operation in all cases where uncertainty prevails as to the practicability of embryulcia, and where, he says, no two practitioners agree as to the actual space in the pelvis. "In short," he says, "where I was not satisfied that a passage existed for a full-grown foetus of 2 inches in the short diameter, and $3\frac{1}{2}$ in length, I should be inclined to adopt the Cæsarean operation in preference to embryulcia." I would draw an entirely different conclusion, and in all cases, whatever the degree of distortion might be either in the brim or outlet of the pelvis, attempt to deliver by embryulcia where the presenting part could be reached by the finger and the crotchet applied. Had the patient survived, and had impregnation again taken place, instead of repeating the Cæsarean operation, as he proposes, premature labour should have been induced in the early months of pregnancy. Dr. M. states, in the history of the case, that the patient suffered little or no inconvenience from this morbid growth during life, or the term of utero-gestation. At times she had colicky pains, and, on questioning her mother as to the probable cause of the exostosis, she admitted that her daughter had received a fall on the back when 6 or 8 years of age, which occasioned pain in the sacral region a short time afterwards.

In Dr. Haber's case of difficult labour from an exostosis of the sacrum, the history of which is contained in an inaugural dissertation published at Heidelberg, 1830, the disease also followed a fall upon the ice some years before, when the woman was carrying a heavy load upon the head. This accident was followed by pain in the back and pelvis, which gradually disappeared. She married, became pregnant, and during labour the whole cavity of the pelvis was found to be filled up with an osseous tumor which grew from the sacrum. The Cæsarean section was performed; but the child was putrid, and the patient died soon after the operation. The length of the tumor was seven inches,

and its greatest breadth six. The highest part of it hangs, as you will see by looking at *this* figure, over the place where the third vertebra of the loins is joined with the fourth. The lowest part of the tumor is distant about two lines and a half from the point of the sacrum. From the posterior surface of the body of the bones of the pubes the tumor is only one line and a half distant. Towards the anterior part, and downwards between the tumor and bones of the pubes, the space is eight or ten lines. The brim of the pelvis was almost completely filled up with the tumor. It appears from the history that there was no other method of delivering this patient but by the Cæsarean section. If the existence of the disease had been known during pregnancy, which however does not appear to have been the case, the induction of premature labour would have been proper in the early months, as soon indeed as the pregnancy was detected, which would have obviated the necessity for the operation. The same observation might be applied to the cases of osteo-sarcomatous tumors of the pelvis obstructing delivery, recorded by Grimm, Stark, and others.

LUMLEIAN LECTURES
DELIVERED AT THE
COLLEGE OF PHYSICIANS,
MARCH 1843,
BY GEORGE BURROWS, M.D.
Physician to St. Bartholomew's Hospital.

LECTURE II.

Recapitulation. Disturbance of the cerebral circulation, by alterations in the relative quantity of blood in the arteries and veins. Reconsideration of the arguments upon which is founded the opinion that the quantity of blood within the cranium does not alter.

Pressure an important principle in sustaining and destroying the functions of the brain. Illustrations of vascular pressure on the brain in health and disease. Observations on the cephalo-spinal serum and its functions. Increased vascular pressure, and its effects. Diminished vascular pressure, and its effects. Syncope produced by insufficient vascular pressure, rather than by a diminished supply of blood to the brain. Examination and explanation of the phenomena of syncope produced under various circumstances. Cerebral disturbance in general anæmia attributed to insufficient vascular pressure more than to anæmia of the cerebral substance.

THE expiration of the hour allotted to a lecture, compelled me, on the former occasion,

to conclude before I had completed a review of the subject which I brought before your notice. I must, therefore, be allowed briefly to recapitulate the points which then occupied our attention.

The subject of my former lecture was the modifications which the circulation within the cranium is capable of undergoing in health and disease, and the state of the circulation within the cranium after different kinds of death.

I quoted from the writings of many eminent physicians the opinions entertained by them on certain peculiarities of the circulation within the head. It appeared from this enquiry that an opinion was very prevalent, "that the quantity of blood within the cranium must be the same, or very nearly the same, at all times, whether in health or disease, in life or after death."

I informed you that this theory of the invariable quantity of blood within the head had been supported, 1st, by reference to certain experiments performed by Dr. Kellie, of Leith; and, 2dly, upon the supposition that the cranium is a complete sphere of bone, which is exactly filled by its contents, the brain, by which that organ is shut up from atmospheric pressure, and from all influence from without, except what is communicated from the blood-vessels which enter it.

I gave, in the first place, a concise analysis of the experiments from which it has been inferred that a state of bloodlessness is not discovered in the brains of animals which have died by hæmorrhage; but, on the contrary, very commonly a state of venous congestion. I then detailed some similar experiments of my own, the results of which were submitted to your inspection, and from which, I flatter myself, it appeared evident that the brains of animals bled to death were deprived of their blood to the extent of rendering them pallid and anæmic. And from these experiments I inferred that it was not a fallacy, as some supposed, that arteriotomy or venesection diminished the actual quantity of blood in the cerebral vessels.

2dly, I detailed some experiments of Dr. Kellie, from which it was attempted to be proved that the quantity of blood in the cranium is not affected by the posture of the head. In opposition to this conclusion I exhibited to you the results of some analogous experiments, from which it was manifest that the quantity of blood in the head is affected to a most extraordinary extent by posture. I showed the effects of gravitation of blood to and from the head.

These results led me to suggest some practical rules which should be adopted in the examination of the cranium after death, where the blood remains fluid, if we wish to

avoid being misled by pseudo-morbid appearances.

3dly, I pointed out how it had been attempted to support the opinion, that the quantity of blood in the cranium is invariable, by adducing the absence of congestion of the cerebral vessels in persons who have died by hanging. Admitting the accuracy of such statements, I related to you the appearances in other instances of death by hanging, which fully proved that not only congestion, but extravasations of blood, were often found in the brains of those that died by hanging. I then attempted to explain the occasional absence of congestion in these cases, (1) by the imperfect compression of all the jugular veins; (2) by the outlet afforded to the blood of the head through that beautiful plexus of sinuses which surrounds the spinal cord; also, (3) especially by the gravitation of the fluid blood during the suspension of the body; and, lastly, by the division of the cervical vessels before the head is opened. I also showed, by experiments, that when precautions were adopted to obviate the influence of such causes, then in death by apnoea there was intense congestion of the cerebral vessels.

Upon the present occasion I will complete my investigation of this interesting topic. And here I must remark, that those who maintain that the absolute quantity of blood in the cerebral vessels does not vary, admit a disturbance of the cerebral circulation in the following manner:—They point out the probability of a frequent alteration in the relative quantities of blood in the cerebral arteries and veins. Thus, they assert that those pathological states which have a tendency to cause influx of blood into the cerebral arteries, and accumulation in those vessels, will accomplish this change at the expense of the cerebral veins. Again, anything causing obstruction of the return of blood from the cranium will produce fulness of the sinuses and cerebral veins, but, at the same time, the quantity in the arteries will be equally diminished. They also maintain, if the quantity transmitted to the brain be lessened, the cerebral arteries will be comparatively empty; but there will be a corresponding fulness of the venous system within the cranium. These opinions of Drs. Abercrombie and Kellie are adopted by Dr. Watson, who supports them by similar reasonings. In states of anæmia, he informs us*, a diminished quantity of blood will be transmitted towards and into the cerebral arteries; but the whole volume of blood in the brain remains the same; therefore blood will accumulate more in the veins. "It is probably in this way that *the appearance of*

* Medical Lectures, op. cit.

the labour is finished. If it is born alive death soon afterwards takes place from extravasation of blood upon the brain, producing apoplexy and convulsions.

The soft parts of the mother surrounding the head become hot, dry, tumid, and inflamed, and all the injurious effects of pressure and interrupted circulation of the blood are sooner or later experienced. You cannot pass up the finger around the head without difficulty, and causing more or less distress to the patient; the discharges from the vagina become acrid and offensive; retention of urine takes place, from the pressure of the head on the neck of the bladder and urethra; the abdomen becomes tender; the tongue loaded with urgent thirst; the pulse rapid and feeble; and more or less general exhaustion ensues. In some cases rupture of the uterus takes place in the course of a few hours after the head has become wedged in the brim of a slightly distorted pelvis. Not unfrequently death follows artificial delivery in no long time, when the head of the child has been allowed to remain too long impacted in the pelvis, and still oftener sloughing of the vagina, bladder, and rectum, takes place.

In cases of slighter distortion of the pelvis, it is impossible to predict at the commencement of labour whether the head will pass or not, and while it continues to advance, and no unfavourable symptoms are present, you ought not to interfere—wait patiently, and see what nature can do. If the head descends so low into the cavity of the pelvis that an ear can be felt, and the os uteri is fully dilated, and there is room to pass up the blades of the forceps without the employment of much force, it is always proper, when delivery becomes necessary, to attempt to extract the head with the forceps. It is necessary, however, to remember that sloughing is apt to follow the use of the forceps, where the soft parts have been long pressed upon by the head, and that perforation of the head is a much safer operation for the mother, when the distortion is considerable.

The employment of the long forceps, in cases of distorted pelvis, has been recommended by Baudelocque, Boivin, Lachapelle, Capuron, Maygrier, Velpeau, and Flammant, whose works contain ample instructions for its use, before the head of the child has entered the brim of the pelvis; and the last of these writers has expressed his belief that the instrument is more frequently required while the head of the child remains above the superior aperture of the pelvis, than after it has descended into the cavity.

In this country there are no practitioners of judgment and experience who have frequent recourse to the forceps, or who employ it before the orifice of the uterus is fully dilated, and the head of the child has de-

scended so low into the pelvis that an ear can be felt, and the relative position of the head to the pelvis accurately ascertained. The instrument is very seldom used in England where the pelvis is much distorted, or where the soft parts are in a rigid and swollen state, but it is had recourse to where delivery becomes necessary in consequence of exhaustion, hæmorrhage, convulsions, and other accidents which endanger the life of the mother. It is used solely with the view of supplying that power which the uterus does not possess.

Where the pelvis is distorted in a high degree, as in some of the specimens before you on the table, where the distance from the base of the sacrum to the symphysis pubis varies from an inch and a half to two inches and a half, the head of a full-grown child cannot enter the brim, however long the labour may be allowed to continue. The membranes burst, and the liquor amnii escapes as in natural labour, and the uterus closely contracts around the body of the child, and acts powerfully upon it, but the head presses upon the uterus at a distance from the orifice, and it is never completely dilated. In some cases, where the labour has lasted from forty-eight to sixty hours, the os uteri has not been more than half dilated, and the whole head of the child, swollen by the pressure, has remained entirely within the uterus above the brim, and pushed forward by the base of the sacrum over the symphysis pubis. This figure from Smellie's twenty-eighth table gives a side view of a distorted pelvis, with the head of a full-grown foetus squeezed into the brim, the parietal bones decussating each other, and compressed into a conical form. "This table shows," says Smellie, "the impossibility, in such a case, to save the child unless by the Cæsarean operation, which ought, however, never to be performed, excepting when it is impracticable to deliver at all by any other method. Even in this case, after the upper part of the head is diminished in bulk, and the bones are extracted, the greatest force must be applied, in order to extract the bones of the foetus and basis of the skull, as well as the body of the foetus." (See top of next page.)

The following figure from Smellie's twenty-second table gives a lateral view of a distorted pelvis, divided longitudinally, with the head of a foetus of the seventh month passing the same. "The head of the foetus here," he says, "though small, is with difficulty squeezed down into the pelvis, and changed from a round to an oblong form before it can pass, there being only the space of two inches and a quarter between the projection of the superior part of the sacrum and ossa pubis. If the head is soon deli-

vered the child may be born alive; but if it continues in this manner many hours, it is in danger of being lost, on account of the long pressure on the brain; to prevent which, if the labour-pains are not sufficiently strong, the head may be helped along with the forceps." "This figure may serve as an example of the extreme degree of distortion of the pelvis, between which and the well-formed one are many intermediate degrees, according to which the difficulty of delivery must increase or diminish, as well from the disproportion of the pelvis and head of the foetus—all which cases require the greatest caution, both as to the safety and management of the mother and child."

Where there exists a great degree of distortion of the brim of the pelvis, you may be unable to determine positively the distance between the base of the sacrum and symphysis pubis; and it is not necessary for practical purposes to do so with mathematical accuracy; but when it is under two inches and a half, you will readily discover,

if you have had considerable experience, on making the ordinary examination, from the unusual manner in which the sacrum projects, that it is impossible for a child at the full period to pass through it. If labour has commenced at the full period of pregnancy, and you discover before it has continued many hours that the pelvis is greatly distorted, and that the child cannot possibly pass alive, no advantage can result from allowing the labour to endure till the patient is exhausted, and you are satisfied that the difficulty cannot be overcome by the powers of the constitution. In such a case delay is dangerous, and there is nothing which can save the woman's life but opening the head of the child with the perforator, and extracting it with the crotchet. But this should never be had recourse to without a regular consultation of experienced practitioners, and before it has been placed beyond all doubt, by the most careful investigation, that the delivery can be accomplished in no other manner so as to preserve the mother's life.

In the greater number of cases of difficult labour from a high degree of distortion of the pelvis which have come under my observation, where it has been the first child, the process has been allowed to go on till the efforts of the patient were nearly discontinued, or had ceased entirely, and the favourable period for operating was lost. In some cases, even when the duration of the labour, and the local and constitutional symptoms, have made it manifest that such interference was justifiable and necessary, I have unfortunately delayed too long to deliver, in consequence of employing the stethoscope, and ascertaining that the child was alive. In cases of extreme distortion of the brim of the pelvis the proper practice is to perforate the head, as soon as the os uteri is sufficiently dilated to admit of the operation being done with safety, and afterwards leaving the patient in labour till the head has partially entered the brim, and the os uteri is considerably dilated. There can be no doubt that, in some cases, it is right to interfere before we certainly know that the child has been destroyed by the pressure; but we have nothing here to do with the question respecting the life or death of the child; our conduct will be biassed if we endeavour to solve this question. We have only to determine positively that delivery is absolutely necessary to save the mother's life, and that it is impossible for the head of the child to pass till its volume is reduced. Paré, Guillemeau, Mauriceau, Portal, Puzos, Levret, Smellie, and all the best accoucheurs who have since appeared in Britain, have performed the operation of craniotomy in many cases of distortion from rickets and malacosteon,

without reference to the condition of the foetus. "True religion, and the common sense of mankind," observes Dr. Denman, "appear to have nothing contradictory. The doctrine they teach of its being our duty to do all the good in our power, and to avoid all the mischief we can, is applicable to the exigencies of every state, and we may be easily reconciled to it on the present occasion. In some cases of difficult parturition it is not possible that the lives both of the mother and child should be preserved. Of the life or death of the mother we can under all circumstances be assured: of the life or death of the child there is often reason to doubt, when we are called upon to decide and to act. The destruction of the mother would not, in the generality of cases which may bring the operation of which we are speaking under contemplation, contribute to the preservation of the child; but the treatment of the child as if it were already dead, with as much certainty of success as is found in other operations, secures the life of the parent. It then becomes our duty, and is agreeable to our reason, to pursue that conduct which will give us the most probable chance of doing good: that is, of saving one life when two lives cannot possibly be preserved."

"The only means of effecting delivery," observes Dr. Collins, "where the disproportion between the head of the child and the pelvis is so great as to prevent us reaching the ear with the finger, is by reducing the size of the head and using the crotchet. This is, however, an operation that *no inducement* should tempt any individual to perform, except the imperative duty of saving the life of the mother when placed in imminent danger. I have no difficulty in stating, and that after the most anxious and minute attention to this point, that where the patient has been properly treated from the commencement of her labour; where strict attention has been paid to keep her cool; her mind easy; where stimulants of all kinds have been prohibited, and the necessary attention paid to the state of the bowels and bladder; that, under such management, the death of the child takes place in laborious and difficult labour before the symptoms become so alarming as to cause any experienced physician to lessen the head. This is a fact which I have ascertained beyond all doubt by the stethoscope, the use of which has exhibited to me the great errors I committed before I was acquainted with its application to midwifery, viz. in delaying delivery, often, I have no doubt, so as to render the result precarious in the extreme, and in some cases even fatal."

The operation of craniotomy is now performed by all British practitioners of reputation, whether the child be alive or dead,

if the condition of the mother is such as to render delivery absolutely necessary, and the head of the child is beyond the reach of the forceps, or where, from distortion of the pelvis, or rigidity of the os uteri and vagina, it cannot be extracted if its volume is not reduced. This operation is performed from a conscientious belief and deep conviction that if neglected to be done at a sufficiently early period the mother's life will be sacrificed, and the life of the mother is considered as much more important than that of the child. Some continental writers affirm, but, I believe, unjustly, that in England we have frequently recourse to craniotomy without due consideration, and without proper regard to the life of the child; and, whatever the state of the parent may be, they refuse to open the head till they can obtain certain evidence, which in some cases it is impossible to obtain, that it is dead. "Nothing could excuse the conduct of the practitioner," says Baudelocque, "who would perforate the head of a child without previously knowing with certainty that it was not alive, a circumstance which can alone authorize us to employ the perforator and crotchet." By following this erroneous principle, the lives of both mother and child would, I believe, in the majority of cases be sacrificed.

In numerous cases of distortion of the pelvis the induction of premature labour has been successfully employed in this country, and it is now ascertained that the operation, which will be described hereafter, is attended with little risk to the mother, and that nearly one half of the children are born alive, and continue to live, where it is performed after the seventh month of pregnancy. In cases of great distortion of the pelvis, the induction of premature labour at an early period of pregnancy, before the sixth month, is likewise known to be a safe operation, and to render craniotomy and the Cæsarean operation wholly unnecessary. The greater number of the best practical writers on midwifery in this country have considered the induction of premature labour applicable only to cases of slighter distortion, and have considered it improper in first pregnancies, and before seven complete months of utero-gestation have elapsed.

Little has been said by them respecting the safety and utility of the operation in cases of great distortion, to obviate the danger to the mother of fatal contusion or laceration of the uterus and vagina, which are always to be dreaded when much force is required after perforation to extract the head of the child. "If the pelvis be so far reduced in its dimensions," observes Dr. Denman, "as not to allow the head of a child of such a size as to give hopes of its living to pass through it, the operation cannot be attended

with success. It is in those cases only in which there is a reduction of the dimension of the pelvis to a certain degree, and not beyond that degree, that this operation ought to be proposed or can succeed." "As the primary object is to preserve the life of the child," says Dr. Merriman, "the operation should never be performed till seven complete months of utero-gestation have elapsed." As early as 1769, it was proposed by Dr. Cooper to induce abortion in cases of extreme distortion of the pelvis. "Before I conclude," he remarks, in his history of a fatal case of Cæsarean section, "allow me to propose the following question, viz. 'In such cases where it is certainly known that a mature child cannot possibly be delivered in the ordinary way alive, would it not be consistent with reason and conscience, for the preservation of the mother, to produce an abortion?'"

I have met with two cases of such great distortion from rickets in the first pregnancy, that I have induced premature labour in the seventh month, and was enabled in consequence to complete the delivery with far less difficulty and danger than it could otherwise have been done. I shall read to you the details of these cases, with the view of impressing upon you the importance of the principle, and of inducing you to perform the same operation at an earlier period of the first pregnancy than the seventh month, if you should meet with any individual whose pelvis is so distorted that a child cannot then pass through it, or in whom the cavity of the pelvis is filled up with large exostoses and tumors. By having recourse to this operation in the early months, even before the fifth month, the Cæsarean operation can never be necessary except in those cases in which the condition of the pelvis has not been ascertained till the full period. In the case of extreme distortion from malacosteon, related by Sir Charles Bell, had the membranes of the ovum been perforated in the second or third month the necessity for the Cæsarean operation would not have occurred, and the progress of the disease would probably, for a time at least, have been arrested.

On Tuesday, January 9, 1833, Mr. Robertson, of Albemarle Street, requested me to see a woman whose pelvis and extremities were greatly distorted by rickets, and who was in the seventh month of her first pregnancy. From an examination of the pelvis, we thought the short diameter of the brim was considerably under three inches, and that a child at the full period could not pass through it without having the volume reduced by craniotomy, and that the operation would be attended by difficulty and danger. We resolved, in consequence, to induce premature labour, though it was the first pregnancy, and though a

rule had been laid down by the most judicious writers that the practice should never be adopted till experience had decidedly proved that the mother was incapable of bearing a full grown child alive. The os uteri was situated high up and directed backward, but I experienced no difficulty in introducing the stiletted catheter, and perforating the membranes. The liquor amnii began to escape immediately after, and continued to flow for three days, and labour pains then came on. For forty-eight hours they were feeble and irregular. Mr. Robertson then found the os uteri considerably dilated, and a foot of the child protruding through it. He extracted the breech and extremities without difficulty, but he could not succeed in drawing the head through the brim unto the cavity of the pelvis. I passed the point of the perforator up to the back part of the head without difficulty, and having made a large opening through the integuments and skull, the brain began to escape. The point of the crotchet was then introduced into the opening, and fixed upon the base; and by drawing downwards and backwards with the crotchet, and at the same time pulling upon the body of the child, the head soon passed through the pelvis, completely flattened on the sides. She recovered without a bad symptom. On the 17th of May, 1839, when the same patient had completed the seventh month of her second pregnancy, I punctured the membranes. The liquor amnii began immediately to escape, and continued to flow till the whole of the following day, and in the evening violent labour pains came on. The nates presented, and Mr. Robertson had no difficulty in extracting the child without perforation of the head. On the 19th, the usual symptoms of ruptured uterus soon appeared, and she died on the 22d. On the 24th, I examined the body with Mr. Robertson, and we found a large rent in the cervix uteri. This is the pelvis which you see now, and the following are its dimensions. The distance from the base of the sacrum to the symphysis pubis measures two inches and one line. The transverse diameter of the brim is five inches and three quarters. At the outlet, a line drawn between the tuberosities of the ischia measures four inches and a half, and another line, from the extremity of the coccyx to the lower edge of the symphysis pubis, three inches and a half. Had premature labour been induced at the end of the fifth month, or earlier, instead of the seventh, it is very probable the fatal accident which occurred would have been prevented.

The following figure gives a pretty correct view of the brim of this pelvis, although it was not taken from it. (See next page.)

The advantage obtained by inducing premature labour in a first pregnancy, where the pelvis is greatly distorted, was still more

striking in the following case:—On Jan. 23, 1842, Mr. Kell, of Bridge Street, Westminster, requested me to see, with him and Dr. Hingeston, a woman, æt. 28, who was in the seventh month of her first pregnancy, and whose pelvis was greatly distorted by rickets. Some days before, Dr. Hingeston had passed a sound into the uterus, and detached the membranes from the lower part, but labour did not take place. I found the os uteri high up, and situated close behind the symphysis pubis. No difficulty was experienced in perforating the membranes in the usual manner, and the liquor amnii afterwards began to escape, and continued to flow till the evening of the 26th, when strong labour pains commenced. At 6 A.M. on the 27th, the os uteri was considerably dilated, and the nates were felt presenting. As it was obvious the breech would never pass through the brim, I brought down the lower extremities with the blunt end of the crotchet, and extracted the trunk without difficulty; but I was obliged also to bring down the arms with the blunt hook. Afterwards I endeavoured to pass up the perforator to the back part of the head, and open it, but could not succeed in getting the point of the instrument beyond the upper cervical vertebra. Being afraid of separating these, and detaching the head from the trunk, I gave up the attempt to perforate the back part of the head, and tried to draw the head through the brim of the pelvis with the crotchet, by fixing the point of the instrument over the bones of the face and forehead. After much exertion, continued for nearly two hours, the head was at last extracted, when completely torn to pieces. I believe it would have been impossible, in this case, to perforate the skull through the roof of the mouth, as has sometimes been done where similar difficulties have presented to perforating the back part of the head. The placenta was soon expelled, and the patient had a perfect and rapid recovery. It is impossible to doubt that the result of this case would have been widely different had the patient been allowed to go on without interference till the end of the ninth month. Being certain that a child of seven months could not pass through the brim of this pelvis, I resolved to induce premature labour at an earlier period, if

consulted in her subsequent pregnancy. On February 7, 1843, Mr. Kell again requested me to see this patient, who had completed her fifth month of gestation. The stiletted catheter was passed up readily into the uterus, but the liquor amnii did not escape. On the 10th, the point of the stilette having been sharpened, the instrument was again introduced, and the membranes readily punctured. The liquor amnii continued to flow till the 12th, when pains came on, and the child was expelled in a few hours, without artificial assistance. The head presented. The recovery was favourable. I was formerly of opinion that in no case of distortion, however great, could it be necessary to induce premature labour before the end of the fifth month of pregnancy, but in cases of extreme distortion from malacosteon, where the sacro-pubic diameter does not exceed an inch and a half, as in *this pelvis* which you now see, I think it would be advisable to put a period to the pregnancy before the fifth month, which can be done with perfect safety to the mother. The woman from whom *this distorted pelvis* was removed perished in consequence of the membranes not having been perforated sufficiently early. The following figure represents the appearance of a distorted pelvis in the possession of Mr. Barlow, and of the pelvis you now see.

Ritgen has given a table of the period of pregnancy at which labour should be induced, according to the degree of narrowing of the sacro-pubic diameter. Labour, he thinks, should be induced at the twenty-ninth week, when the diameter of the pelvis is two inches and seven lines; in the thirtieth week, when it is two inches and eight lines; in the thirty-first, when it is two inches and nine lines; in the thirty-fifth, when two inches and ten lines; in the thirty-sixth, when two inches and eleven lines; and in the thirty-seventh, when the sacro-pubic diameter is exactly three inches. When it is above three inches, the case must be left to nature.

Mr. Barlow has also published a synoptical table. In a well-formed pelvis, where the distance from the upper edge of the symphysis pubis to the superior part of the os sacrum, or conjugate diameter of the pelvis, is from five to four inches, delivery will take place, he says, by the efforts of nature alone

where the conjugate diameter is from four or four to three or two inches and three quarters, the delivery may be completed by the efforts of nature, or assisted with the forceps or lever ; where from two and three quarters to two and a half inches, premature labour should be induced ; where from two and a half to one and a half inches, by embryulcia, or delivery with the crotchet ; and where the conjugate diameter of the brim is from one and a half inches to the lowest possible degree of distortion, by the Cæsarean operation.

Mr. Barlow thinks this table will facilitate further inquiry, although he justly observes that the practitioner should bear in mind the absolute impossibility of determining the mean degree of compressibility which the cranium of the foetus may undergo by the efforts of the uterus ; and he very properly points out the necessity of making a very careful examination in each case before adopting any decided plan of treatment.

Baudelocque regarded the induction of premature labour as a useless, if not an injurious, operation ; and M. Dugès has recently characterised it as fatal to the mother, and the source of most frightful abuse. In the tables of the Maternité, by Baudelocque, Boivin, and Lachapelle, including nearly 60,000 cases of labour, there is no account of any case in which premature labour was induced. The last of these writers begins her strictures on the practice by declaring that she had never either employed "that method, or seen others have recourse to it." The propriety of inducing premature labour was brought under the consideration of the Academy of Medicine, Paris, in 1827, and they decided that the practice was unjustifiable under any circumstances.

The discordance which exists between Continental and British practitioners is also strikingly displayed respecting the Cæsarean section. The reports of 258 cases of this operation have been collected by Michaelis, 144 of which occurred in the last, and 110 in the present century. Of these cases, 140

proved fatal. Velpeau states that the operation was performed twenty-eight times between 1810 and 1820 ; and thirty-one times from 1821 to 1830. Dr. Churchill says the operation was performed 316 times between 1750 and 1841, and that the mortality was 52·8 per cent. for the mothers. I believe that it would have been much greater if all the unfortunate cases had been published, which has not been done. In Great Britain the reports of at least 27 cases have been published, and in 25 of them it was fatal to the mother. Other fatal cases have occurred which have not been recorded. I believe there is no practitioner of reputation now in this country who would recommend the operation upon the living body if delivery could be effected by the perforator and crotchet. Wherever the presenting part can be reached, to apply the perforator and crotchet, an attempt should always be made to deliver, and the Cæsarean operation reserved for those cases in which the distortion is so great that the os uteri and presenting part are entirely beyond our reach.

Most of you have already examined the following table, which has been published in the first of these clinical reports, exhibiting a comparative view of the frequency of forceps and craniotomy cases in some of the principal lying-in hospitals in Europe. It may be useful once more to compare the practice of different institutions, that you may be convinced that the first principles of operative midwifery have not yet been established, at least that they are not generally understood, and that there is no other branch of surgery at the present time in such a rude condition. In one hospital the forceps was employed once in every seven cases, and in another once only in 728 cases. How important it is that you should watch the progress of protracted and difficult labours, and discover the best method of treatment, and form correct opinions on the use of instruments, it is not necessary for me now to point out to you more particularly.

Hospitals.	Number of labours.	Forceps cases.	Proportion.	Craniotomy cases.	Proportion.
Dublin, Clarke.	10,199	14	1 in 728	49	1 in 248

Only a few cases have been recorded in which *Exostoses*, or *Osteo-sarcomatous Tumors of the pelvis*, have produced difficult

labour, and I have not met with any instance in practice.

Dr. M'Kibbin has related an example in

the Edin. Med. and Surg. Journal, April 1831, where the hollow of the sacrum and right side of the brim of the pelvis were occupied by an exostosis of a conical form. The woman had been in labour 50 hours, and the greatest space afforded for the passage of the child was on the right side, and it was only $1\frac{1}{2}$ or $1\frac{3}{4}$ of an inch. From the apex of the tumor to the lower part of the symphysis pubis $1\frac{1}{2}$ inch; from the brim of the pelvis on the right side, immediately over the foramen thyroideum to the lateral surface of the tumor at its widest part, $1\frac{1}{2}$ inch; more posteriorly $1\frac{1}{2}$ inch. The delivery was completed by the Cæsarean operation, but the child was dead, and the woman died after, the unsuccessful result being attributed to the delay. Dr. M. advocates the early adoption of the Cæsarean operation in all cases where uncertainty prevails as to the practicability of embryulcia, and where, he says, no two practitioners agree as to the actual space in the pelvis. "In short," he says, "where I was not satisfied that a passage existed for a full-grown fœtus of 2 inches in the short diameter, and $3\frac{1}{2}$ in length, I should be inclined to adopt the Cæsarean operation in preference to embryulcia." I would draw an entirely different conclusion, and in all cases, whatever the degree of distortion might be either in the brim or outlet of the pelvis, attempt to deliver by embryulcia where the presenting part could be reached by the finger and the crotchet applied. Had the patient survived, and had impregnation again taken place, instead of repeating the Cæsarean operation, as he proposes, premature labour should have been induced in the early months of pregnancy. Dr. M. states, in the history of the case, that the patient suffered little or no inconvenience from this morbid growth during life, or the term of utero-gestation. At times she had colicky pains, and, on questioning her mother as to the probable cause of the exostosis, she admitted that her daughter had received a fall on the back when 6 or 8 years of age, which occasioned pain in the sacral region a short time afterwards.

In Dr. Haber's case of difficult labour from an exostosis of the sacrum, the history of which is contained in an inaugural dissertation published at Heidelberg, 1830, the disease also followed a fall upon the ice some years before, when the woman was carrying a heavy load upon the head. This accident was followed by pain in the back and pelvis, which gradually disappeared. She married, became pregnant, and during labour the whole cavity of the pelvis was found to be filled up with an osseous tumor which grew from the sacrum. The Cæsarean section was performed; but the child was putrid, and the patient died soon after the operation. The length of the tumor was seven inches,

and its greatest breadth six. The highest part of it hangs, as you will see by looking at *this* figure, over the place where the third vertebra of the loins is joined with the fourth. The lowest part of the tumor is distant about two lines and a half from the point of the sacrum. From the posterior surface of the body of the bones of the pubes the tumor is only one line and a half distant. Towards the anterior part, and downwards between the tumor and bones of the pubes, the space is eight or ten lines. The brim of the pelvis was almost completely filled up with the tumor. It appears from the history that there was no other method of delivering this patient but by the Cæsarean section. If the existence of the disease had been known during pregnancy, which however does not appear to have been the case, the induction of premature labour would have been proper in the early months, as soon indeed as the pregnancy was detected, which would have obviated the necessity for the operation. The same observation might be applied to the cases of osteo-sarcomatous tumors of the pelvis obstructing delivery, recorded by Grimm, Stark, and others.

LUMLEIAN LECTURES

DELIVERED AT THE
COLLEGE OF PHYSICIANS,

MARCH 1843,

BY GEORGE BURROWS, M.D.
Physician to St. Bartholomew's Hospital.

LECTURE II.

Recapitulation. Disturbance of the cerebral circulation, by alterations in the relative quantity of blood in the arteries and veins. Reconsideration of the arguments upon which is founded the opinion that the quantity of blood within the cranium does not alter.

Pressure an important principle in sustaining and destroying the functions of the brain. Illustrations of vascular pressure on the brain in health and disease. Observations on the cephalo-spinal serum and its functions. Increased vascular pressure, and its effects. Diminished vascular pressure, and its effects. Syncope produced by insufficient vascular pressure, rather than by a diminished supply of blood to the brain. Examination and explanation of the phenomena of syncope produced under various circumstances. Cerebral disturbance in general anæmia attributed to insufficient vascular pressure more than to anæmia of the cerebral substance.

THE expiration of the hour allotted to a lecture, compelled me, on the former occasion,

to conclude before I had completed a review of the subject which I brought before your notice. I must, therefore, be allowed briefly to recapitulate the points which then occupied our attention.

The subject of my former lecture was the modifications which the circulation within the cranium is capable of undergoing in health and disease, and the state of the circulation within the cranium after different kinds of death.

I quoted from the writings of many eminent physicians the opinions entertained by them on certain peculiarities of the circulation within the head. It appeared from this enquiry that an opinion was very prevalent, "that the quantity of blood within the cranium must be the same, or very nearly the same, at all times, whether in health or disease, in life or after death."

I informed you that this theory of the invariable quantity of blood within the head had been supported, 1st, by reference to certain experiments performed by Dr. Kellie, of Leith; and, 2dly, upon the supposition that the cranium is a complete sphere of bone, which is exactly filled by its contents, the brain, by which that organ is shut up from atmospheric pressure, and from all influence from without, except what is communicated from the blood-vessels which enter it.

I gave, in the first place, a concise analysis of the experiments from which it has been inferred that a state of bloodlessness is not discovered in the brains of animals which have died by hæmorrhage; but, on the contrary, very commonly a state of venous congestion. I then detailed some similar experiments of my own, the results of which were submitted to your inspection, and from which, I flatter myself, it appeared evident that the brains of animals bled to death were deprived of their blood to the extent of rendering them pallid and anæmic. And from these experiments I inferred that it was not a fallacy, as some supposed, that arteriotomy or venesection diminished the actual quantity of blood in the cerebral vessels.

2dly, I detailed some experiments of Dr. Kellie, from which it was attempted to be proved that the quantity of blood in the cranium is not affected by the posture of the head. In opposition to this conclusion I exhibited to you the results of some analogous experiments, from which it was manifest that the quantity of blood in the head is affected to a most extraordinary extent by posture. I showed the effects of gravitation of blood to and from the head.

These results led me to suggest some practical rules which should be adopted in the examination of the cranium after death, where the blood remains fluid, if we wish to

avoid being misled by pseudo-morbid appearances.

3dly, I pointed out how it had been attempted to support the opinion, that the quantity of blood in the cranium is invariable, by adducing the absence of congestion of the cerebral vessels in persons who have died by hanging. Admitting the accuracy of such statements, I related to you the appearances in other instances of death by hanging, which fully proved that not only congestion, but extravasations of blood, were often found in the brains of those that died by hanging. I then attempted to explain the occasional absence of congestion in these cases, (1) by the imperfect compression of all the jugular veins; (2) by the outlet afforded to the blood of the head through that beautiful plexus of sinuses which surrounds the spinal cord; also, (3) especially by the gravitation of the fluid blood during the suspension of the body; and, lastly, by the division of the cervical vessels before the head is opened. I also showed, by experiments, that when precautions were adopted to obviate the influence of such causes, then in death by apnoea there was intense congestion of the cerebral vessels.

Upon the present occasion I will complete my investigation of this interesting topic. And here I must remark, that those who maintain that the absolute quantity of blood in the cerebral vessels does not vary, admit a disturbance of the cerebral circulation in the following manner:—They point out the probability of a frequent alteration in the relative quantities of blood in the cerebral arteries and veins. Thus, they assert that those pathological states which have a tendency to cause influx of blood into the cerebral arteries, and accumulation in those vessels, will accomplish this change at the expense of the cerebral veins. Again, anything causing obstruction of the return of blood from the cranium will produce fulness of the sinuses and cerebral veins, but, at the same time, the quantity in the arteries will be equally diminished. They also maintain, if the quantity transmitted to the brain be lessened, the cerebral arteries will be comparatively empty; but there will be a corresponding fulness of the venous system within the cranium. These opinions of Drs. Abercrombie and Kellie are adopted by Dr. Watson, who supports them by similar reasonings. In states of anæmia, he informs us*, a diminished quantity of blood will be transmitted towards and into the cerebral arteries; but the whole volume of blood in the brain remains the same; therefore blood will accumulate more in the veins. "It is probably in this way that *the appearance of*

* Medical Lectures, op. cit.

congestion in the superficial veins of the brain is brought about in animals that are bled to death." That such venous congestion does not exist, I venture to affirm from the experiments I have performed, and the results of which have already been laid before you.

Some have gone further, and not only asserted that hæmorrhage causes venous congestion of the brain, but have also maintained the paradox, that animals bled to death die of apoplexy. True, indeed, it is that they die with symptoms analogous to those of apoplexy, and this is no new discovery, for this physiological fact was known to Hippocrates. That great man very concisely and tersely expresses the fact in one of his aphorisms, "*Σπασμὸς γίνεται ἢ ὑπὸ πληρωσίου, ἢ κενωσίου.*"—Sec. vi.

Hippocrates, in this sentence, announced the remarkable pathological truth, that depletion or repletion of the vascular system produces similar symptoms of disturbance of the nervous centres.

Not only have the principles of hydrostatics and other immutable laws of physics been invoked to support the theory that the absolute quantity of blood within the cranium is invariable, or nearly so, but the symbols of algebra have been made to perform their precise evolutions to show that when any increase takes place in the quantity of blood in the arteries of the brain, there must be a corresponding decrease in the veins. If a decrease in the arteries, then an increase in the veins. Thus it is said, if the whole quantity of blood within the cranium = C , a constant, the quantity of blood in the arteries = x , the quantity of blood in the veins = y , then $C = x + y$ always; but let x be diminished by a quantity (a) then y must be increased by this quantity (a), otherwise the original supposition, $C = x + y = (x - a) + (y + a)$ would not be maintained.

Hence, according to the theory supported by this algebraical equation, if the carotid arteries be divided, and the quantity of blood in the cerebral arteries be thus diminished, the quantity of blood in the cerebral veins will be equally increased. But the results of experiments negative these speculations, and show that a diminution of the quantity of blood in one set of vessels is not necessarily accompanied by a state of repletion of the other system of vessels.

There must, then, be some fallacy in this part of the argument; and the question naturally arises, where is that to be found? I admit, with Dr. Abercrombie and others, the probability of a disturbance in the equilibrium between the quantities of blood in the arterial and venous systems within the cranium, and that such disturbance is productive of many serious cerebral symptoms.

But in such cases, I presume, there is also a change in the absolute quantity of blood within the cranium, and not a mere change in the relative quantities in the two systems of vessels.

I believe the error of this part of the argument, which I have been combating, consists in the first supposition, that the quantity of blood in the cranium is a constant quantity. On the contrary, I think that experiments and physiological considerations lead us to the conclusion that the quantity of blood within the cranium is extremely variable at different times, and under different circumstances.

The experiments which support this opinion have been already detailed.

Those who have maintained this doctrine of the constant quantity of blood within the cranium, have not, I believe, taken into due consideration that large proportion of the contents of the cranium which consists of extra-vascular serum. We know that in health the quantity which exists in the ventricles, membranes, and substance of the brain, is considerable*. Regarding this serum as an important element of the contents of the cranium, I admit that the whole contents of the cranium, that is, the brain, the blood, and this serum together, must be at all times nearly a constant quantity.

But variations in the quantity of serum within the cranium are quite compatible with health; and in morbid states of the brain we know that at one time the cerebral substance, its membranes, and ventricles, will be nearly devoid of serum; while, at another time, these parts abound with serous effusion. In accordance with the variations in the quantity of extra-vascular serum, there must be fluctuations in the quantity of intra-vascular fluid, the blood. From this consideration alone, it seems that the blood may be increased or diminished in the cranium. The increase or decrease may affect the two systems of vessels, arterial and venous, equally, or the equilibrium may be disturbed; there may be excess in either arteries or veins, without any necessary diminution in the quantity of blood contained in the other set of vessels.

Let us now reflect how this question stands. It has been said that the brain is enclosed in a complete sphere of bone, the cranium, which removes it from the influence of atmospheric pressure, and hence no material change can take place in the absolute quantity of blood circulating in the vessels of the brain. This proposition is

* From the researches of M. Majendie, it would appear that in the healthy adult the cerebro-spinal serum is never under ii. oz., and often amounts to v. oz. in persons of large frame of body.

also supported by appeal to experiments, and mathematical calculation.

(1). It is maintained, that when hæmorrhage takes place from the general system, it does not affect the quantity of blood in the brain. The experiments I have performed lead me to the opposite conclusion.

(2). Posture of the body after death is said not to affect the quantity of blood within the head. My experiments show that posture has a most striking influence on the quantity of blood in the cerebral vessels.

(3). It has been attempted to prove that when individuals die of asphyxia, or apnoea, there is no excessive congestion of the cerebral vessels. Numerous observations show that in the different kinds of death by apnoea there is great congestion of the cerebral vessels, and that where it is absent it may be accounted for on anatomical and physical principles.

(4). It has also been attempted to prove, by an algebraical equation, that if the quantity of blood be diminished in one system of cerebral vessels, it will be increased in the other vessels. In reply to this, I have shown that the results of experiments negative this conclusion. The error lies in the false assumption of the elements of which the equation is formed.

But how shall we account for these variations in the quantity of blood within the head, if the cranium be a complete sphere, as it has been described by some physiologists?

Does the anatomical structure of the human cranium warrant the opinion that it is a complete sphere, capable of removing its contents from the influence of atmospheric pressure? I think not. The numerous fissures and foramina for the transmission of vessels and nerves through the bones of the cranium appear to me to do away with the idea of the cranium being a perfect sphere, like a glass globe, to which it has been compared by some writers. If there were not always an equilibrium of pressure on the parts within and without the cranium, very serious consequences would arise at the various foramina of the skull. Are, then, the contents of the cranium removed from the influence of atmospheric pressure? I think not, from other considerations. Atmospheric pressure is undoubtedly exerted on the blood in the vessels entering the cranium. This pressure, by a well-ascertained law in hydrostatics, must be transmitted in all directions through the fluid blood, and hence to the blood and other contents within the cranium. If, in the natural state of the parts, the brain is defended from atmospheric pressure, should we not expect to find the functions of that organ disturbed in some way when part of the walls of this sphere is wanting? But in children with open fontanelles, and in adults

who have lost part of the bones of the cranium, we observe no peculiar disturbance of the functions of the brain from this gap in the walls of the imaginary sphere. But, lastly, the effects of gravity on the fluid contents of the cranium, and the effects of the cupping-glass, which will often draw blood from the vessels of the dura mater, causing ecchymosis there, assures us that the cranium is not a perfect sphere in the sense in which it has been supposed.

If, then, I have proved, as I believe, that the quantity of blood within the cranium; so far from being a constant, or nearly constant quantity, is, on the contrary, as variable as in other parts of the body, the pathology of many serious affections of the brain will require revision.

The principle of *pressure* is one of much importance, both in sustaining and destroying the functions of the brain.

The functions of the brain probably cannot be maintained in a healthy state without a certain amount of pressure on the cerebral substance. Any variation of pressure which we can artificially produce and estimate appears to affect the functions of this organ. Under the ordinary conditions of health, the cerebral substance is defended from the influence of all variations of external mechanical pressure, and is only subjected to causes of pressure acting within the cranium. A principal and constant cause of pressure from within is the momentum of the blood distending the arteries and veins within the skull. But some of the best writers on the pathology of the brain have maintained that this force, as a cause of pressure, is inoperative—first, because “the cerebral substance is principally composed of inelastic fluids which are incompressible”; and, secondly, “because the brain is incompressible by any such force as can be conveyed to it from the heart through the carotid and vertebral arteries.”

Let us analyse these arguments. In the first “the brain is said to be incompressible, because its substance is principally composed of inelastic fluids.”

The greatest confusion exists among medical writers on this part of the physiology of the brain, arising from the misapplication and misconception of the terms incompressible and inelastic. Those properties of bodies which we term incompressibility and elasticity bear no constant proportion to each other. It is well known that some of the most incompressible bodies are highly elastic, and those which are very compressible are also elastic.

Thus an ivory billiard ball is very incompressible, but highly elastic; and again, a sponge is very compressible, but also highly elastic. Hence there is neither direct nor inverse proportion subsisting between

the compressibility and elasticity of bodies. It should not therefore be affirmed, that the incompressibility of the contents of the cranium depends on the inelasticity of the substance of which those contents are composed. In truth, the contents of the cranium, although very incompressible, are highly elastic. As long as medical writers employ the terms of the physical or exact sciences thus loosely, it will be extremely difficult to arrive at the real meaning of experimentalists.

The second part of this argument is, "that the brain is incompressible by any such force as can be conveyed to it from the heart through the carotid and vertebral arteries." The consideration of this opinion I approach with some diffidence, because it emanated from no less an authority than Dr. Abercrombie. The force which is impressed on the cerebral substance, through the carotid and vertebral arteries, is derived from the contractile power of the left ventricle of the heart, at whatever amount that power be estimated. The static force of the blood in the aorta was estimated by Hales at 50 lbs.; Poisseuille's recent experiments place this force at only 5 lbs.

It is not of great importance to my argument whether the momentum of the blood in the aorta be estimated at the greater or less amount.

I wish to show that such a force is actually operating on the cerebral substance within the cranium, and then estimate its effects, when increased or diminished. When a portion of the cranium has been removed, either by accident or artificially, and the dura mater exposed to view, phenomena are remarked which indicate pressure on the cerebral substance by a force from within the cranium, and that the force varies at different times. With every systole of the heart the surface of the dura mater rises a little, and has a tendency to transgress the level of the bones of the cranium. It again subsides with each diastole. Also during the act of expiration, while the free return of venous blood from the brain is impeded, the surface of the dura mater rises and subsides with the succeeding inspiration. Thus whatever has a tendency to distend the cerebral vessels, whether arterial or venous, appears to exert a pressure on the cerebral substance, which is manifested in the manner I have just described.

But the effects of this pressure on the cerebral substance are even more manifest after those accidents, where, with loss of a portion of the bones of the cranium, there is also a laceration of the dura mater. In such cases the distending force of the vessels, acting on the cerebral substance, is so manifest, that not only do we witness the alternate rise and fall of the exposed surface corresponding with the heart's systole and

diastole, but portions of the substance of the brain are actually protruded through the aperture in the cranium. *Hernia cerebri*, or protrusion of the convolutions of the brain, is effected by a force from within, just as hernia of the convolutions of the intestines is produced when the walls of the abdomen are perforated.

Such phenomena more strongly assure us that considerable pressure on the cerebral substance is produced by vascular distension. If the force distending the cerebral arteries be diminished, while the foregoing phenomena are under observation, the manifestations of pressure from within are diminished in proportion.

Thus in the experiment of Dr. Kellie, when he trephined the cranium of a dog, he observed the alternate rising and subsidence of the dura mater at the opening; but having divided one of the carotid arteries of the dog, there was an evident gradual sinking of the brain from the level of the cranium, indicating a diminution of the distending force. Lastly, it has been observed that when syncope occurs, this alternating motion of the brain ceases, and again returns when the heart's action is renewed.*

The existence of such a force within the cranium producing outward pressure must be admitted; but Dr. Abercrombie and some others affirm that the brain is not compressible by this force. Although I cannot allow that the brain is altogether incompressible, still I admit that it is only slightly so; but although so little compressible, the cerebral substance must sustain the pressure of this force equally as if it were of the most compressible materials. On this part of the argument Dr. Alexander Monro very justly remarked, "the less compressible we suppose the substance of the brain to be, the more readily we understand how the whole of it may be affected by a plethora or increased momentum of blood in it." (*Observations on Nervous System*, p. 6.)

Injurious effects of this pressure on the brain would be much more often exhibited, when the quantity of the blood within the cranium is by any means increased, were it not for the peculiarity of the venous system in the cranium, which affords such ready escape for the redundant blood, and for another anatomical peculiarity of the contents of the cranium. The peculiarity which I now advert to is hardly sufficiently estimated by pathologists: it is the very large portion of the contents of the cranium, which is re-

* The whole of this subject of the influence of the respiration and circulation on the mass of the brain is admirably discussed by that profound and laborious writer, Albert Haller, in his *Elementa Physiologiae*, vol. 4, in the sections "*Refluxus sanguinis venosi, qui a respiratione pendet*," and again in the section "*Motus cerebri arteriosus*."

movable by absorption, or by other causes. I advert to the extra-vascular fluid in the cranium; the serum in the substance, ventricles, and membranes of the brain. This fluid, very appropriately designated *cephalo-spinal*, varies greatly in amount at different times; and probably a portion readily changes its site from the cranium to the spinal canal, and conversely. This is not a mere hypothesis to support a theory or explain a difficulty.

Anatomy points out that the serum in the arachnoid may readily pass from the cranium to the spinal canal; also that that which is contained in the cerebral ventricles may through the fourth ventricle partly escape towards the membranes of the spinal cord. The experiments of Majendie show that this cerebro-spinal fluid may be artificially abstracted or increased.

Pathological states of the spinal column give us an opportunity of ascertaining the freedom of transmission of serum from the arachnoid of the cord to the brain. In spina bifida we remark during fits of coughing and crying the spinal tumor becomes much more tense, and by graduated pressure with the hand over the tumor it may be gradually decreased in size. With the diminution of size we may witness symptoms of pressure on the brain and cord. These considerations lead to the conclusion that this cephalo-spinal fluid may, under the influence of pressure, change its site. When arterial or venous congestion of the brain is suddenly induced, the first consequence will be increased pressure on all the contents of the cranium; the second effect will be the displacement of a portion of this extra-vascular serum into the spinal canal. When abstraction of blood from the cranium is effected, a quantity of serum occupies the vacated space. This extra-vascular serum is supplemental to the other contents of the cranium, removable by pressure or absorption, at one time giving place to the increased quantity of blood, at another making up for the deficiency of blood in the vessels. This extra-vascular serum is merely so as supplemental to the varying quantity of blood, but also to the variable quantity of nervous matter in the brain. Thus in hypertrophy of the brain there is a corresponding deficiency of serum: the serum in the membranes and ventricles is so limited of this fluid, that they are a great try. On the contrary, in atrophy of the brain, the ventricles and membranes are distended with it.

I think it probable that this extra-vascular fluid may perform another office. Partly through this serum a more intimate pressure is preserved on the cerebral substance, and for the support of the arachnoid of pressure may be the consequence of the arachnoid, and of those causes which

ventricles, which dip into the central parts of the cerebral mass.*

The effects of increased determination of blood to the brain, or of obstructed venous circulation from it may be witnessed, even in otherwise healthy states of that organ, although those effects are probably sometimes obviated by the anatomical conditions I have just explained: but they are most strikingly displayed when there is pre-existing disease in the cranium.

When the power of the heart is inordinately increased by stimulants, general plethora, or hypertrophy of the left ventricle, we remark a train of symptoms similar to those produced by varying degrees of mechanical pressure artificially exerted on the brain.

When obstruction to the return of blood from the brain takes place, so that the blood becomes almost stagnant in the sinuses, the force of the left ventricle (which in the normal state of the cerebral circulation is expended partly in propelling the blood onward through the capillaries towards the right auricle, and partly in distending the vessels within the cranium) is under such circumstances expended upon the interior surface of the cerebral blood-vessels. This pressure is partly sustained by the resistance of the vascular tissues, and the remainder is borne by the surrounding cerebral substance.

Whatever this force may be, it becomes a source of increased pressure upon the cerebral substance; and the more so, according to the pre-existing morbid states of the encephalon. When the circulation is excited or obstructed an excessive state of congestion of the integuments of the head and face is produced, and from the experiments I have detailed, it may, I think, be inferred, that a simultaneous congestion of the internal vessels of the cranium is formed.

In perfectly healthy conditions of the cranium, when it contains nothing but the brain and normal quantity of serum fluid, the cerebral substance may readily resist the force of a temporary increase of blood in the vessels. In atrophy of the brain, or in the presence of a morbid state of the brain, the resistance is lessened, and the force of the blood in the vessels is increased, and the result is a morbid state of the brain.

In some pathological states of the brain, when there is an increase of the quantity of blood in the vessels, the force of the blood in the vessels is increased, and the result is a morbid state of the brain.

In some pathological states of the brain, when there is an increase of the quantity of blood in the vessels, the force of the blood in the vessels is increased, and the result is a morbid state of the brain.

brain, tumors and cysts in that organ, and in large extravasations of blood on the surface, every cause which is capable of exciting the heart's action produces an increased disturbance of the functions of the brain. The variable character of the symptoms of cerebral disturbance in these permanent lesions within the cranium are thus probably accounted for by the variable vascular pressure. Dr. Watson has offered a nearly similar explanation of the occasional recurrence of cerebral symptoms, although their supposed cause, organic disease in the cranium, is permanent. It seems to me probable that many permanent lesions within the cranium do not affect the functions of the brain by pressure, except when there is some cause in operation capable of inducing vascular congestion, or when the lesion is of a mechanical nature, or is gradually increasing.

If the force of the contractions of the heart be diminished in these morbid states of the encephalon, there is usually a corresponding relief to the cerebral symptoms; but should the same diminution in the force of the circulation be produced in healthy states of the brain, the functions of the organ are suddenly annihilated from insufficient vascular pressure: syncope is the result.

Syncope is occasioned by insufficient vascular pressure on the brain, and not from the inadequate quantity of blood supplied to the brain and its vessels, as is commonly supposed.

In the most simple form of syncope, that which arises from a strong moral emotion in a previously healthy person, we see the single effect of want of due vascular pressure on the brain. In such cases the quantity and quality of the blood in the person's body are unaltered previous to the syncope, and the suspension of the cerebral functions arises solely from the diminished energy of the heart. The blood is no longer propelled with sufficient force from the left ventricle to maintain an adequate pressure on the cerebral substance. If such a person happen to be in the erect posture, the syncope is more rapid and complete; because the enfeebled muscular tissue of the heart is unable to sustain the arterial current of blood against the force of gravity, and to preserve the proper degree of pressure on the brain. Let such a fainting person be placed in the horizontal posture, and, as is well known, consciousness quickly returns. But why? Because the enfeebled heart is equal to maintain the arterial current of blood in that favourable posture, and with it the requisite amount of vascular pressure on the brain. The same phenomena occur in syncope produced by hæmorrhage, although in this case it is not so easy to show that the suspension

of the cerebral functions is occasioned solely by want of vascular pressure on its substance. It has been forcibly pointed out by Dr. Marshall Hall, that bleeding in the erect posture is the best method of ascertaining the power of the system to sustain the loss of blood, and of the propriety of bleeding as a remedial agent. It is a matter of daily experience that a small amount of blood taken from a person in the erect posture will cause syncope; whereas double the amount of blood might have been taken from that person in the horizontal posture, without producing a similar result. Hence the posture of the individual, and not the amount of blood abstracted, is the more efficient cause of the syncope. The effects of the erect posture on the heart and brain I have just described.

In extreme states of debility, from whatever cause produced, the mere sudden assumption of the erect posture is often adequate to induce an alarming, and sometimes fatal, syncope. In this posture the feeble heart is unable to project the blood against the force of gravity in the carotid and vertebral arteries, when the brain is suddenly deprived of the vascular pressure essential to the continuance of its functions. The influence of this cause of death was not unfrequently seen in our cholera hospitals, when that disease prevailed epidemically. Patients who were in states of collapse, but still in the enjoyment of sensorial functions while reclining, upon assuming the erect posture died almost instantaneously.

There is another posture of the body which will, in some persons, induce syncope, and where the cause appears to be the sudden diminution of the momentum of the blood in the arteries of the head, and, consequently, an insufficient vascular pressure on the brain. If the arms be held extended in vertical lines above the head, this posture will quickly produce faintness in some persons. Here the heart has suddenly imposed upon it the additional labour of overcoming the effects of gravity on the blood in the arteries of the upper extremities; and the consequence is a diminution of the momentum of the blood in the arteries of the head.

It is unnecessary for me particularly to describe the remarkable disturbance of the functions of the brain which takes place in general anæmia. Does the long catalogue of nervous symptoms arise from the altered qualities of the blood in anæmia; or from an insufficient quantity of blood in the cerebral substance; or, lastly, from impaired vascular pressure on the substance of the brain? Without underrating the injurious effects of the altered qualities of the blood, in general anæmia, on the brain and all the organs of the body, still I am inclined to the opinion that some of the most remarkable symptoms

arise rather from insufficient vascular pressure than from an insufficient quantity of blood in the substance of the brain.

Simple anæmia of the brain certainly does not produce that train of symptoms which is usually ascribed to a want of due supply of blood to the brain. Probably there is no condition of the brain, not even that induced by repeated hæmorrhage, in which the substance of the organ is so completely anæmic as in genuine hypertrophy of the brain. In this rare cerebral affection the membranes and substance are found dry, and devoid of blood or serum; the medullary matter is as white and firm as blanc-mange or hard-boiled white of egg. The cranium is already so completely filled by hypertrophy of the cerebral substance that the blood is unable to make its way through the vessels; and with all this bloodlessness of the organ, we witness none of the nervous symptoms of general anæmia. On the contrary, the symptoms are rather those commonly ascribed to the effects of inordinate supply of blood to the brain. In these cases of hypertrophy of the brain the force of the heart is unimpaired; the blood is propelled with its normal force into the cerebral arteries, but it cannot make its way through the capillaries; and thus the static force of the heart is expended on the surrounding cerebral substance: so that, in anæmia of the brain from this cause, there are none of the symptoms present which accompany anæmia of the organ produced by hæmorrhage, in which condition there is insufficient power of the heart to produce the amount of vascular pressure essential to the functions of the brain. Hence we infer that the simple condition of anæmia of the brain, independent of diminished vascular pressure, is insufficient to produce the peculiar train of symptoms so often observed in general anæmia.

It is in general anæmia, caused by profuse hæmorrhage, that we witness the fearful catalogue of symptoms indicating disturbance of the nervous centres in their most aggravated form. In such a condition of the body, we remark that whatever tends temporarily to assist the heart, or stimulate it to propel the blood towards the brain, alleviates the nervous symptoms; on the contrary, whatever places the heart at greater disadvantage in propelling the blood to the brain, aggravates these nervous symptoms. The loss of consciousness in syncope, the convulsions after hæmorrhage, are often immediately terminated by the horizontal posture so favourable to the momentum of the blood in the carotid arteries. The senses of sight and hearing are often impaired or lost during states of general anæmia, but posture alone will sometimes restore these functions of the brain.

Dr. Abercrombie* relates the following remarkable instance of the effects of posture on the cerebral functions. A gentleman, aged 30, came to Edinburgh for advice in regard to an obscure affection, referred chiefly to the stomach, and which had reduced him to a state of extreme weakness and emaciation. As his debility had advanced he had become considerably deaf, and this affected him in a singular manner. When standing, or sitting upright, he was very deaf; but when he lay horizontally, with his head very low, he heard perfectly. If, when standing, he stooped forward, so as to produce flushing of his face, his hearing was perfect; and upon raising himself again he continued to hear distinctly as long as the flushing continued: as this went off, the deafness returned.

In the foregoing case Dr. Abercrombie supposed there must be a want of balance in the circulation within the brain, a diminished quantity of blood and momentum of blood in the cerebral arteries, with a corresponding increase of the blood in the cerebral veins.

I think the history of this case of deafness, as recorded by Dr. Abercrombie, rather shows that the varying amount of vascular pressure was the cause both of the suspension and restoration of the cerebral functions.

For a number of curious and interesting cases illustrating the state of the nervous centres when the system is reduced to a state of general anæmia, either by loss of blood or other debilitating causes, the work of Dr. Marshall Hall "On the Loss of Blood, &c." may be consulted with advantage. In one and all of these cases of disturbed functions of the brain, an immediate, but temporary, relief to the symptoms is afforded by horizontal posture, stimulants, and other means which favour the momentum of the blood moving through the carotid and vertebral arteries.

We may remark similar effects from diminished vascular pressure on the brain in the application of that powerful, but hazardous contrivance, the horizontal revolving bed. Dr. Darwin, I believe, invented this rotatory machine for the purpose of tranquillizing the nervous system and procuring sleep†. It was subsequently employed to calm the violence of the furious maniac. Its mode of application is as follows. The patient is laid on his back, with his head close to a column or pivot, around which the bed is made to revolve in a horizontal plane with considerable velocity. A centrifugal force is thus generated, which, from the position of the patient, determines the blood from the head towards the lower

* Op. cit.

† Zoonomia, vol. ii. p. 608.

brain, tumors and cysts in that organ, and in large extravasations of blood on the surface, every cause which is capable of exciting the heart's action produces an increased disturbance of the functions of the brain. The variable character of the symptoms of cerebral disturbance in these permanent lesions within the cranium are thus probably accounted for by the variable vascular pressure. Dr. Watson has offered a nearly similar explanation of the occasional recurrence of cerebral symptoms, although their supposed cause, organic disease in the cranium, is permanent. It seems to me probable that many permanent lesions within the cranium do not affect the functions of the brain by pressure, except when there is some cause in operation capable of inducing vascular congestion, or when the lesion is of a mechanical nature, or is gradually increasing.

If the force of the contractions of the heart be diminished in these morbid states of the encephalon, there is usually a corresponding relief to the cerebral symptoms; but should the same diminution in the force of the circulation be produced in healthy states of the brain, the functions of the organ are suddenly annihilated from insufficient vascular pressure: syncope is the result.

Syncope is occasioned by insufficient vascular pressure on the brain, and not from the inadequate quantity of blood supplied to the brain and its vessels, as is commonly supposed.

In the most simple form of syncope, that which arises from a strong moral emotion in a previously healthy person, we see the single effect of want of due vascular pressure on the brain. In such cases the quantity and quality of the blood in the person's body are unaltered previous to the syncope, and the suspension of the cerebral functions arises solely from the diminished energy of the heart. The blood is no longer propelled with sufficient force from the left ventricle to maintain an adequate pressure on the cerebral substance. If such a person happen to be in the erect posture, the syncope is more rapid and complete; because the enfeebled muscular tissue of the heart is unable to sustain the arterial current of blood against the force of gravity, and to preserve the proper degree of pressure on the brain. Let such a fainting person be placed in the horizontal posture, and, as is well known, consciousness quickly returns. But why? Because the enfeebled heart is equal to maintain the arterial current of blood in that favourable posture, and with it the requisite amount of vascular pressure on the brain. The same phenomena occur in syncope produced by hæmorrhage, although in this case it is not so easy to show that the suspension

of the cerebral functions is occasioned solely by want of vascular pressure on its substance. It has been forcibly pointed out by Dr. Marshall Hall, that bleeding in the erect posture is the best method of ascertaining the power of the system to sustain the loss of blood, and of the propriety of bleeding as a remedial agent. It is a matter of daily experience that a small amount of blood taken from a person in the erect posture will cause syncope; whereas double the amount of blood might have been taken from that person in the horizontal posture, without producing a similar result. Hence the posture of the individual, and not the amount of blood abstracted, is the more efficient cause of the syncope. The effects of the erect posture on the heart and brain I have just described.

In extreme states of debility, from whatever cause produced, the mere sudden assumption of the erect posture is often adequate to induce an alarming, and sometimes fatal, syncope. In this posture the feeble heart is unable to project the blood against the force of gravity in the carotid and vertebral arteries, when the brain is suddenly deprived of the vascular pressure essential to the continuance of its functions. The influence of this cause of death was not unfrequently seen in our cholera hospitals, when that disease prevailed epidemically. Patients who were in states of collapse, but still in the enjoyment of sensorial functions while reclining, upon assuming the erect posture died almost instantaneously.

There is another posture of the body which will, in some persons, induce syncope, and where the cause appears to be the sudden diminution of the momentum of the blood in the arteries of the head, and, consequently, an insufficient vascular pressure on the brain. If the arms be held extended in vertical lines above the head, this posture will quickly produce faintness in some persons. Here the heart has suddenly imposed upon it the additional labour of overcoming the effects of gravity on the blood in the arteries of the upper extremities; and the consequence is a diminution of the momentum of the blood in the arteries of the head.

It is unnecessary for me particularly to describe the remarkable disturbance of the functions of the brain which takes place in general anæmia. Does the long catalogue of nervous symptoms arise from the altered qualities of the blood in anæmia; or from an insufficient quantity of blood in the cerebral substance; or, lastly, from impaired vascular pressure on the substance of the brain? Without underrating the injurious effects of the altered qualities of the blood, in general anæmia, on the brain and all the organs of the body, still I am inclined to the opinion that some of the most remarkable symptoms

arise rather from insufficient vascular pressure than from an insufficient quantity of blood in the substance of the brain.

Simple anæmia of the brain certainly does not produce that train of symptoms which is usually ascribed to a want of due supply of blood to the brain. Probably there is no condition of the brain, not even that induced by repeated hæmorrhage, in which the substance of the organ is so completely anæmic as in genuine hypertrophy of the brain. In this rare cerebral affection the membranes and substance are found dry, and devoid of blood or serum; the medullary matter is as white and firm as blanc-mange or hard-boiled white of egg. The cranium is already so completely filled by hypertrophy of the cerebral substance that the blood is unable to make its way through the vessels; and with all this bloodlessness of the organ, we witness none of the nervous symptoms of general anæmia. On the contrary, the symptoms are rather those commonly ascribed to the effects of inordinate supply of blood to the brain. In these cases of hypertrophy of the brain the force of the heart is unimpaired; the blood is propelled with its normal force into the cerebral arteries, but it cannot make its way through the capillaries; and thus the static force of the heart is expended on the surrounding cerebral substance: so that, in anæmia of the brain from this cause, there are none of the symptoms present which accompany anæmia of the organ produced by hæmorrhage, in which condition there is insufficient power of the heart to produce the amount of vascular pressure essential to the functions of the brain. Hence we infer that the simple condition of anæmia of the brain, independent of diminished vascular pressure, is insufficient to produce the peculiar train of symptoms so often observed in general anæmia.

It is in general anæmia, caused by profuse hæmorrhage, that we witness the fearful catalogue of symptoms indicating disturbance of the nervous centres in their most aggravated form. In such a condition of the body, we remark that whatever tends temporarily to assist the heart, or stimulate it to propel the blood towards the brain, alleviates the nervous symptoms; on the contrary, whatever places the heart at greater disadvantage in propelling the blood to the brain, aggravates these nervous symptoms. The loss of consciousness in syncope, the convulsions after hæmorrhage, are often immediately terminated by the horizontal posture so favourable to the momentum of the blood in the carotid arteries. The senses of sight and hearing are often impaired or lost during states of general anæmia, but posture alone will sometimes restore these functions of the brain.

Dr. Abercrombie* relates the following remarkable instance of the effects of posture on the cerebral functions. A gentleman, aged 30, came to Edinburgh for advice in regard to an obscure affection, referred chiefly to the stomach, and which had reduced him to a state of extreme weakness and emaciation. As his debility had advanced he had become considerably deaf, and this affected him in a singular manner. When standing, or sitting upright, he was very deaf; but when he lay horizontally, with his head very low, he heard perfectly. If, when standing, he stooped forward, so as to produce flushing of his face, his hearing was perfect; and upon raising himself again he continued to hear distinctly as long as the flushing continued: as this went off, the deafness returned.

In the foregoing case Dr. Abercrombie supposed there must be a want of balance in the circulation within the brain, a diminished quantity of blood and momentum of blood in the cerebral arteries, with a corresponding increase of the blood in the cerebral veins.

I think the history of this case of deafness, as recorded by Dr. Abercrombie, rather shows that the varying amount of vascular pressure was the cause both of the suspension and restoration of the cerebral functions.

For a number of curious and interesting cases illustrating the state of the nervous centres when the system is reduced to a state of general anæmia, either by loss of blood or other debilitating causes, the work of Dr. Marshall Hall "On the Loss of Blood, &c." may be consulted with advantage. In one and all of these cases of disturbed functions of the brain, an immediate, but temporary, relief to the symptoms is afforded by horizontal posture, stimulants, and other means which favour the momentum of the blood moving through the carotid and vertebral arteries.

We may remark similar effects from diminished vascular pressure on the brain in the application of that powerful, but hazardous contrivance, the horizontal revolving bed. Dr. Darwin, I believe, invented this rotatory machine for the purpose of tranquillizing the nervous system and procuring sleep†. It was subsequently employed to calm the violence of the furious maniac. Its mode of application is as follows. The patient is laid on his back, with his head close to a column or pivot, around which the bed is made to revolve in a horizontal plane with considerable velocity. A centrifugal force is thus generated, which, from the position of the patient, determines the blood from the head towards the lower

* Op. cit.

† Zoonomia, vol. ii. p. 608.

extremities. This centrifugal force, thus suddenly created, powerfully diminishes the momentum of the blood moving into the cranium: the diminished arterial pressure on the cerebral substance soon produces a sense of exhaustion or complete syncope.

I have adduced this as another illustration of the principle, that the suspension of the functions of the brain is produced by the diminished vascular pressure on its substance, rather than by an inadequate supply of blood to the organ. In this last described experiment it is clear that neither the quantity nor the quality of the blood in the vascular system is affected by the generation of this new power. Neither can we ascribe the loss of cerebral functions to an alteration in the balance of the circulation within the cranium, that is, to an alteration in the relative quantities of blood in the arteries and veins. This centrifugal force must have an equal effect upon the blood in the arteries and veins of the brain, as well as upon the removable serum. I think we can only ascribe the effects to diminished vascular pressure.

On this interesting and important principle of pressure, I have endeavoured to point out that such a force is constantly in operation upon the cerebral substance; that this pressure is produced by vascular distension; that, in health, any cause which is capable of increasing or diminishing this vascular distension has the effect of disturbing the functions of the brain; that these effects of vascular distension would be more serious and frequent if parts of the contents of the cranium were not readily removable upon increase of vascular pressure; that, in pre-existing structural diseases of the encephalon, any increase of vascular distension causes much more serious disturbance of the cerebral functions, and the symptoms so produced are analogous to those of mechanical pressure on the brain.

I have also attempted to support the opinion that variations of this vascular pressure are the causes of the intermitting character of the symptoms in cases of permanent disease within the cranium.

Lastly, I have endeavoured to explain the phenomena of syncope, however produced, on the principle of diminished momentum of blood in the arteries of the head, and consequent diminished vascular pressure on the cerebral substance, rather than on the principle that the brain is not supplied with a sufficient quantity of blood.

ON THE
CAUSES OF STRANGULATION AND
DEATH IN CASES OF HERNIA,
OR THE
SIGNS OF CONSTITUTIONAL OR
HUMORAL DISORDER IN SUCH
CASES.

(Some Statistics; the Treatment; Dr.
O'Beirne's Views, &c.)

By T. WILKINSON KING, Esq.

(For the London Medical Gazette.)

IN the Guy's Hospital Reports for the year 1838, I published some statistics to show that most herniæ exist for years before they become subject to violent strangulation; that the mean duration of three-fourths of the well-recorded cases had been between 15 and 25 years before danger arose.

The following were my conclusions from a considerable series of facts*.

"First, Most herniæ being of old-standing before they become seriously strangulated, this result is not attributable to the state of the sac, but to that of the bowel; in which defective nourishment and power of vessels leads to more ready tumefaction; and all this seems attributable to the age and the organic deterioration belonging to it.

"Secondly, The common and chief danger is from a peculiar and unhealthy kind of peritonitis; the consequence, probably, of the same constitutional decay or decline of organs which induced the strangulation.

"Thirdly, The above facts lead to the conclusion, that prompt surgery, to remove the cause of inflammation, and the most cautious medicine to obviate, and not excite, inflammation, and to add nothing to the oppressed condition of the patient, are indications even more pressing than has been hitherto maintained, at least among authors and the generality of surgeons."

I am now enabled to extend the facts of my case, and, I hope, add strength to an argument which, if it has hitherto found no favour, has met no opponents, and which, if just, is important enough to claim attention, both for its own sake and for the reason

* See Guy's Hospital Reports, No. 7, p. 390.

effects more or less light on the sections of declining life.

It would be a consideration of importance, if it were only that the ordinary duration of life before strangulation is 15 or 16 years; especially if we take into the account the fact that the age for strangulation is most commonly after the 10th or 40th year of life.

One grand fact of my case is, that in half of the cases of hernia that have required immediate aid, it proved to have pre-existed for a period of 15 or 25 years, or even 40 years.

This is as undeniable as it is important; and it seems to me as striking a fact, that the mass of surgical writers seem to have thought it insignificant. But it is a cumulative argument that I think of the greatest import.

Regular exertion and local congestion are the causes of hernia: but when, after a long time, or after a long period of serious strangulation, at some times out of five, is produced years later, when a totally different state of parts and constitution has become developed. The acute inflammation of young persons, and its train of comparatively healthy phenomena, may find its analogy on rare occasions at any period of life. It is characterized by narrow stricture and reparative actions, and may be one of all the morbid traits of old age. A hernia when strangulated, is more like what is called intussuscepted hernia, but devoid of healthy and fraught with signs of non-vital inflammations,—diffused acutely organized and pernicious effusions.

The symptoms, the course, and the external appearances of the latter are more specific.

With numerical facts will, I think, give this view in a somewhat stronger form than my former tables.

It occurred 4 times as often in males as females

„ often in the first year of life†

„ rarely after this, and more and more so till the 9th year.

Numbers increase after the 9th year

„ still more between 13 and 20 (in males only—exertion)

„ „ 20 and 28 (in both sexes—pregnancy.)

„ Males increased by $\frac{1}{4}$,

„ Females „ $\frac{1}{2}$

„ „ 28 and 29 (and most in females)

„ stationary from 30 to 35 = $27\frac{1}{2}$ per annum } 4 males to 1 female

„ increase from 35 to 40 = 52 „ } 3 males to 1 female

„ „ 40 to 50 = 96 „ } 3 males to 1 female

In the last number of the Guy's Hospital Reports*, 44 successive cases are detailed. There appear to have been—

7 cases, more or less recent;

1 „ had existed for some time;

28 „ „ stated numbers of years.

The mean duration of all these is 13 yrs.

2 cases had existed for some years; and

6 „ „ several or a number of years.

Of the same cases there were—

Submitted to operation 18

Successfully (one, æt. 9) 9

Unsuccessfully (the gut rent in one, æt. 21) 9

The mean age in the 8 cases of successful operations was 43 years

Unsuccessful 59½

22 reductions by taxis, &c. 43½

Three other cases were in the last stage, unreduced and fatal; one was a reduction fatal by continued inflammation.

In the years prior to that in which the last cases occurred, there were admitted into Guy's 55 cases of urgent herniæ in two years, or 112 weeks: 17 between November and May, and 5 between June and October. And by setting the dates of these cases beside those of the cases lately published in our Reports, I find that of 100 cases twice as many instances of strangulation are admitted between November and April as between May and October; and that half of the whole number are admitted between December and March inclusive. The increased numbers of winter I refer, as disorganizing pneumonia, to humoral circumstances influenced by the season.

M. Malgagne's statistics may be made to throw some light on these views, but, for the most part, only indirectly. We find that of an immense number of recorded cases in Paris, between the end of 1835 and that of 1837—

* No. 1 of the New Series, April 1843.

† Chiefly umbilical and inguinal, doubtless; and from conformation.

Here we have a mixture of all kinds of cases—simple hernia, with instances of transitory and severer strangulation—but we may perceive that the simple cases decline in annual numbers after the 30th year, and that the largest amount of cases occur to the surgeon on all accounts (of strangulation, &c.) between the 40th and 50th years of life. From calculations of cases at Guy's Hospital, after the publication of my former paper, I find the mean ages of 26 cases fatal on various accounts to be 56½ years, and that of 26 serious cases which recovered to be 44½.

From my printed table I find that the mean ages of the 47 patients successfully operated on was 42½, or 42 years 6 weeks; and that the mean age of those 33 who were fatally operated on, was 45½, or 45 years 6 months. These last sets were chiefly recorded by authors as serious cases; yet I think the difference of age points to the same fact as an analysis of 70 other fatal cases now before me, in which defective reparation, unorganisable effusions, and deteriorated solid viscera, seem to be essential constitutional concomitants of old hernia becoming seriously strangulated.

Dr. Norman Chevers has lately recorded in the Guy's Hospital Reports the circumstances of a large number of unsuccessful or fatal cases of accident and operation. With disordered viscera, imperfect secretion and depurative elimination are palpable inductions in these cases,* and too forcible and important as arguments of humoral deterioration to be omitted or even ranked low as the causes of mischief, whether affecting cases of accidental injury, operation, or parturition, or such even as those of catarrh, pneumonia, or hæmorrhage, or epischeses.

In my former paper I thus expressed myself on this subject:—"The proneness to erysipelas or visceral inflammations, under most operations, marks them (herniæ), as well as many more who are the subject of operations at the

like ages in great cities. Yet all these constitutional dispositions, as they are called, are found on inspecting the dead to be connected with very tangible and permanent alterations of the great viscera. These actual disorganizations are not incompatible with seeming health, but are highly obnoxious when reparation is in progress. If one organ is found affected after death, the change is proportionately more considerable: if several are involved, they are mostly less affected. It is to be remembered, however—though, as after all fatal operations, the changes are less severe and advanced than when the visceral affection alone seems fatal—yet they are so manifest that the wonder is that they were not alone destructive, and *that* much sooner: at least this has been my own reflection on many occasions."

Before the fatal period, herniæ descend almost with impunity, but at length, as in the great injuries, or rather as in cases of slight injury which have become dangerous, the reparative resources being unequal to the task, all the events till death sufficiently indicate the specific state.

It may be in a manner a test of a surgeon's principles for him to ask himself this question. Is there any fear of diffused inflammation from a circumscribed injury to the peritoneum in a healthy person? My answer is, there is no fear whatever; but I do not say, if the patient have been unduly exposed before, or during the treatment, or if subjected to violent medicines, that he is a healthy person, and doubtless there are other similar considerations. What some persons intend when they declare that certain tissues are prone of themselves to spreading inflammation, is still a problem. At one time the assertion is true of all tissues; at another it is not true of any. Of course disease is more serious in certain tissues, and also less happily repaired.

The opinion for which I contend involves of course specific rules of treatment, as I have formerly indicated. In the anticipation of fatal peritonitis, mild, speedy, and efficient remedies are the objects to be held in view. Every kind of aggravation from delay, violence, exposure to cold, or severe remedies, is to be regarded as highly dangerous. I have formerly said as much on this part of my subject as may be desirable,

* These principles have been long taught at Guy's, and the facts on which they are based run through a series of 30 or 40 large volumes of museum manuscripts which are not merely careful records of common facts. Thirteen of these volumes are, perhaps, the most valuable (no slight praise) of all the labours of Hodgkin: and I may claim an equal quantity as my own work. A tabular analysis of the whole for more than twenty years, kept up since I was a pupil, renders the examination of the whole available almost at a glance. Dr. C.'s exposition is principally based on my own autopsy-histories.

until the main principle is admitted to be a sound and essential one. I shall conclude, therefore, with some remarks on a recent theory of strangulation.

Dr. O'Beirne*, of the Richmond Hospital Dublin, some time since recommended the use of the rectum tube to facilitate the reduction of the "intestinal hernia," by giving exit to the retained gases; a simple practice, which if we were to judge from the experience recorded, cannot fail to be occasionally very useful. This distinguished surgeon's views, however, seem to me almost to demand some comments; which I have set down just in the current in which they occurred to me. If any should concur with me in recommending a trial of the practice named, they will probably see no great objection to the following brief inquiry relative to its application, the cases concerned being of so frequent occurrence and great importance, and the causes of strangulation being still subjects of useful and interesting research.

In Dr. O'Beirne's account of the causes and treatment of strangulation in hernia, he attributes the strangulation to the easy access of flatus into the incarcerated portion of bowel, and he recommends the use of the rectum tube for the relief of this air-distended portion.

It will, I think, be in conformity with the opinion of most surgical pathologists, to regard the neck of the sac in hernia as quite passive in the production of strangulation, so that we are all prepared to look for some other cause of this serious state. What commonly produces strangulation? Dr. O'Beirne says flatus does it; but of course this will not apply to the simple omental hernia; nor will it, I suppose, explain the process when only a segment of the intestinal cylinder is involved.

It is an ingenious experiment to make a perforated card represent the aperture of hernia, and then, having passed a knuckle of intestine through it, to shew the effect of rather forcibly inflating this portion of bowel; but in

connection with this, the Dr. asserts that it is not commonly the case, in strangulated hernia, that the intestinal tube is rendered impervious by the compression about the neck of the sac, and he has concluded "that no proposition in nature can be clearer than this: namely, *that as strangulation is produced by a distending force acting from within outwards, and separating the parietes of the constricted gut, and maintaining them at a greater or less distance from each other, there must be a communication.*" Now I suppose it admitted on all sides, 1st, that pressure from within the abdomen first protrudes about as much bowel as the ring will easily contain; 2dly, that whatever may constitute the protrusion, it will generally happen that with the increase of the protrusion there will be a certain increase of calibre or mass in that part actually included in the plane of the constricting ring; and 3dly, that with the very commencement of strangulation there begins also injection and swelling, or even additional fleshiness, of all the intestinal tunics included in the sac. I do not think that these facts warrant the assumption of a persistent "channel of communication" between the bowel in the sac and that in the abdomen, which communication Dr. O'Beirne admits must be extremely narrow. I would suggest that the *distending force* acting from within outwards may at times find a substitute in the increasing turgescence of the strangling gut*, and it cannot but be remarked that a communication between the general bowels and the strangulated portion which may transmit air, and which according to the Dr.'s experience does admit of the passage of air from the strangulated bowel, with the use of the rectum tube, certainly ought to allow of the free escape of air and fluids by the application of ordinary taxes, and still more certainly when exposed by operation. In thus adverting to what I deem erroneous, I would allow that the use of the rectum tube in hernia,

* The second part of Dr. O'Beirne's proposition above, declares the strangulated tube to be of necessity distended, and he seems to infer with air. In answer to this I would say, that the gurgling sound of air, on reduction, is often absent, and that in operations it is commonly evident that the inflation is not more remarkable than the fluid secretions in the bowel, and lastly, that the extreme thickening of its membranes is by far the most notable inherent source of difficulty in the return.

* Article 8th.—In the Dublin Journal of Medical and Chemical Science, for September 1838. "On the primary causes of strangulation, and on an improved mode of performing the Taxis in cases of Intestinal Hernia. By James O'Beirne, M.D. one of the Surgeons to the Richmond Surgical Hospital, &c. Dublin."

in the manner advised and illustrated by examples, may be still a valuable adjunct to surgery.

A few remarks on the deductions to be made from the cases related in corroboration of the Dr.'s views, will serve to introduce a somewhat different explanation of the result. I do not know if it is to be regretted that hitherto we have no account of the different cases in which the rectum tube is not calculated to be successful. I suppose, however, there are some; as, particularly, very small hernia, and acute cases in the young. Again, it may be quite just to conclude that the taxis, successful with the use of the tube, might in a few cases have been ultimately effectual alone. Many of the case recorded to the advantage of the tube, were for hernia in very aged patients; a circumstance involving general tympanitis almost necessarily, considering the nature of the case. Indeed, the tympanitis would appear in some measure essential to the establishment of Dr. O'Beirne's main position. With regard to the use of the tube in young hernia patients, I am tempted to infer that the result must often disappoint us, and I have to add, by way of caution, that I have known the tube (resembling that of the common stomach-pump), penetrate the rectum and peritoneum, and in very careful hands too.

A trial of the rectum tube in strangulated hernia has the advantages of requiring no delay, not interfering with other remedies, and above all it is comparatively safe; for with proper knowledge and care the thick bulbous tube of Dr. O'Beirne cannot, I think, go wrong.

It is scarcely necessary to contend for a different explanation of the use of this instrument: the cases narrated seem to prove that it has been serviceable, as far, surely, as such a number well can. My own explanation would be briefly this: that the sudden diminution of abdominal distension by evacuation per anum (as by mouth), must facilitate the taxis, and if we suppose the evacuation of flatus to be great, and the reduction attempted simultaneously, the beneficial tendency is almost certain. Of course there will often be a difficulty in determining the precise share of influence attributable to remedies when combined, and there must be some difficulty in ascertaining

well the effect of the tube with regard to the quantity of gas to which it gives exit; for I deem it important to observe that after death by strangulation of the small intestine, the whole colon is for the most part remarkably empty; as I have very often demonstrated on inspection during the last few years.

SOME PRACTICAL REMARKS ON THE EMPLOYMENT OF ARSENIC IN THE TREATMENT OF THE DISEASES OF THE SKIN.

By JOHN E. ERICHSEN.

(*For the London Medical Gazette.*)

Among the many remedies that have been had recourse to in the treatment of the diseases of the skin, there are none about the propriety of employing which more discrepancy of opinion has been excited than about arsenic. By some, this metal has been extolled as being, in one or other of the various forms in which it is administered, an agent of the greatest value in controlling the affections in question; and by these it is resorted to, much too indiscriminately, in the treatment of every obstinate cutaneous complaint, without reference to the nature, causes, and actual condition of the disease itself, or to the habit of body and constitution of the individual in whom it occurs. By others, again, the arsenical preparations are looked upon as being frequently useless and dangerous, or, at best, as remedies of uncertain power, which are only to be had recourse to when every other available means of checking the disease for which it may be thought advisable to prescribe them has failed. This difference of opinion appears to me to have arisen from the fact, that sufficient care has not been taken by writers on the diseases of the skin to point out, not only the particular disease in which these remedies are admissible, but, more especially, the particular stage of the complaint in which alone their administration may be expected to be productive of some salutary effect, as well as the kind of constitution and temperament by which only they can be borne. For it does not require a very extended observation

of cutaneous affections to become aware of the fact that an arsenical preparation may be useless, if not highly injurious, in an early stage of a disease, whereas, at a later period, it may be exceedingly beneficial; and that even then it cannot be administered with safety in some constitutions, or to individuals of particular temperament. And in this, I say it with deference, lies the great defect of many of the therapeutic measures inculcated in different treatises on the diseases of the skin; that remedies of the utmost power are abundantly enumerated, but as no directions are usually given as to the precise stage of the disorder in which they should be administered, or notice taken of the circumstances that indicate or contraindicate their employment, the reader is apt to imagine that the author bases his mode of treatment rather upon the particular name that the complaint may chance to bear, than upon any circumstances connected with its stage or cause, or with the habit of body of the patient; and thus he is led to think that if he can once make out the diagnosis, and learn the name of any cutaneous affection that may fall under his observation, the proper treatment of the disease follows as a matter of course, without reference to any modifying circumstances. It is on account of the disappointment that is apt to be consequent upon such a mode of procedure that many remedies, which have been deservedly recommended to the profession as of the utmost power, have had their justly earned character depreciated, either by being administered without sufficient discrimination during improper stages of the disease, or to individuals who were, from constitution, ill able to bear them. It is my intention, then, in the remarks that I am about to make, to direct particular attention to the several circumstances, whether in the constitution or habit of body of the individual, or in the nature or stage of the particular affection under which he may be labouring, or in its complication with other diseases, that may indicate, or contra-indicate, the employment of the preparations of arsenic. For it is from a want of due consideration to these circumstances that this most powerful and valuable class of remedies has been frequently accused of having received a reputation beyond its deserts, or that, at best, it

has been allowed to be capable of curing local diseases but at the expense of more or less permanent derangement of the digestive and nervous functions.

It is to Adair and Girdlestone that we owe, at about the commencement of the present century, the introduction of the preparations of arsenic in the treatment of the diseases of the skin, and from the extraordinary effects that they were shown to possess in removing and controlling affections of this kind, even though of many years' standing, they soon came into general repute, being resorted to, almost as specifics, in those cases of cutaneous disease that had resisted other means of treatment, and even in such as would readily have yielded to less active measures.

The preparations of arsenic that are most commonly had recourse to in the treatment of cutaneous complaints are, the solution of the arsenite of potassa (Fowler's solution), the solution of the iodide of arsenic and mercury (Donovan's solution), the iodide of arsenic and arsenious acid in the form of pill. Besides these, the solution of the arseniate of soda (Pearson's solution) has been recommended by some, and that of the arseniate of ammonia by others, chiefly by Biett; but as these two last are not much employed, and as their qualities and mode of action seem in no way to differ from those of the arsenite of potassa, I shall omit all consideration of them.

The opinions of authors vary somewhat as to the dose in which we should commence the administration of the solution of the arsenite of potassa, and as to the extent to which we ought to carry it. Girdlestone recommends us to begin with the smallest doses, and never to increase the quantity taken beyond five or six drops three times a day, and only to persevere in such quantities as can be taken without inconvenience to the patient. In children, he says, the dose should not exceed two or three drops once or twice a day. The largest quantity he ever gave was twelve drops three times a day; but he soon found that half this quantity would suffice equally well. Bateman and Thomson advise us to begin with doses of four or five drops, which may be slowly increased up to eight, twice a day. Biett, who advocates the employment of arsenic more generally than any other writer, directs

in the manner advised and illustrated by examples, may be still a valuable adjunct to surgery.

A few remarks on the deductions to be made from the cases related in corroboration of the Dr.'s views, will serve to introduce a somewhat different explanation of the result. I do not know if it is to be regretted that hitherto we have no account of the different cases in which the rectum tube is not calculated to be successful. I suppose, however, there are some; as, particularly, very small hernia, and acute cases in the young. Again, it may be quite just to conclude that the taxis, successful with the use of the tube, might in a few cases have been ultimately effectual alone. Many of the case recorded to the advantage of the tube, were for hernia in very aged patients; a circumstance involving general tympanitis almost necessarily, considering the nature of the case. Indeed, the tympanitis would appear in some measure essential to the establishment of Dr. O'Beirne's main position. With regard to the use of the tube in young hernia patients, I am tempted to infer that the result must often disappoint us, and I have to add, by way of caution, that I have known the tube (resembling that of the common stomach-pump), penetrate the rectum and peritoneum, and in very careful hands too.

A trial of the rectum tube in strangulated hernia has the advantages of requiring no delay, not interfering with other remedies, and above all it is comparatively safe; for with proper knowledge and care the thick bulbous tube of Dr. O'Beirne cannot, I think, go wrong.

SOME PRACTICAL REMARKS
ON THE
EMPLOYMENT OF ARSENIC IN
THE TREATMENT OF THE
DISEASES OF THE SKIN.

BY JOHN E. ERICHSEN.

(*For the London Medical Gazette.*)

AMONG the many remedies that have been had recourse to in the treatment of the diseases of the skin, there are none about the propriety of employing which more discrepancy of opinion has been excited than about arsenic. By some, this metal has been extolled as being, in one or other of the various forms in which it is administered, an agent of the greatest value in controlling the affections in question; and by these it is resorted to, much too indiscriminately, in the treatment of every obstinate cutaneous complaint, without reference to the nature, causes, and actual condition of the disease itself, or to the habit of body and constitution of the individual in whom it occurs. By others, again, the arsenical preparations are looked upon as being frequently useless and dangerous, or, at best, as remedies of uncertain power, which are only to be had recourse to when every other available means of checking the disease for which it may be thought advisable to prescribe them has failed. This difference of opinion appears to me to have arisen from the fact, that sufficient care has not been taken by writers on the diseases of the skin to point out, not only the particular disease in which these remedies are admissible, but, more especially, the particular stage of the complaint in which alone their administration may be expected to be productive of some salutary effect, as well as the kind of constitution and temperament by which only they can be borne. For it does not require a very extended observation

of cutaneous affections to become aware of the fact that an arsenical preparation may be useless, if not highly injurious, in an early stage of a disease, whereas, at a later period, it may be exceedingly beneficial; and that even then it cannot be administered with safety in some constitutions, or to individuals of particular temperament. And in this, I say it with deference, lies the great defect of many of the therapeutic measures inculcated in different treatises on the diseases of the skin; that remedies of the utmost power are abundantly enumerated, but as no directions are usually given as to the precise stage of the disorder in which they should be administered, or notice taken of the circumstances that indicate or contraindicate their employment, the reader is apt to imagine that the author bases his mode of treatment rather upon the particular name that the complaint may chance to bear, than upon any circumstances connected with its stage or cause, or with the habit of body of the patient; and thus he is led to think that if he can once make out the diagnosis, and learn the name of any cutaneous affection that may fall under his observation, the proper treatment of the disease follows as a matter of course, without reference to any modifying circumstances. It is on account of the disappointment that is apt to be consequent upon such a mode of procedure that many remedies, which have been deservedly recommended to the profession as of the utmost power, have had their justly earned character depreciated, either by being administered without sufficient discrimination during improper stages of the disease, or to individuals who were, from constitution, ill able to bear them. It is my intention, then, in the remarks that I am about to make, to direct particular attention to the several circumstances, whether in the constitution or habit of body of the individual, or in the nature or stage of the particular affection under which he may be labouring, or in its complication with other diseases, that may indicate, or contra-indicate, the employment of the preparations of arsenic. For it is from a want of due consideration to these circumstances that this most powerful and valuable class of remedies has been frequently accused of having received a reputation beyond its deserts, or that, at best, it

has been allowed to be capable of curing local diseases but at the expense of more or less permanent derangement of the digestive and nervous functions.

It is to Adair and Girdlestone that we owe, at about the commencement of the present century, the introduction of the preparations of arsenic in the treatment of the diseases of the skin, and from the extraordinary effects that they were shown to possess in removing and controlling affections of this kind, even though of many years' standing, they soon came into general repute, being resorted to, almost as specifics, in those cases of cutaneous disease that had resisted other means of treatment, and even in such as would readily have yielded to less active measures.

The preparations of arsenic that are most commonly had recourse to in the treatment of cutaneous complaints are, the solution of the arsenite of potassa (Fowler's solution), the solution of the iodide of arsenic and mercury (Donovan's solution), the iodide of arsenic and arsenious acid in the form of pill. Besides these, the solution of the arseniate of soda (Pearson's solution) has been recommended by some, and that of the arseniate of ammonia by others, chiefly by Biett; but as these two last are not much employed, and as their qualities and mode of action seem in no way to differ from those of the arsenite of potassa, I shall omit all consideration of them.

The opinions of authors vary somewhat as to the dose in which we should commence the administration of the solution of the arsenite of potassa, and as to the extent to which we ought to carry it. Girdlestone recommends us to begin with the smallest doses, and never to increase the quantity taken beyond five or six drops three times a day, and only to persevere in such quantities as can be taken without inconvenience to the patient. In children, he says, the dose should not exceed two or three drops once or twice a day. The largest quantity he ever gave was twelve drops three times a day; but he soon found that half this quantity would suffice equally well. Bateman and Thomson advise us to begin with doses of four or five drops, which may be slowly increased up to eight, twice a day. Biett, who advocates the employment of arsenic more generally than any other writer, directs

us to commence with three drops of the solution every morning before breakfast, and to augment this, every fifth or sixth day, by two or three drops, until twelve or fifteen were taken daily; more than this, he says, should not be administered, and it may be expedient to interrupt the use of the medicine, in these doses, from time to time. Rayer recommends doses of from four to five drops daily, to be gradually increased until the patient takes fifteen drops in four divided doses. Thus, then, although these authorities differ somewhat as to the precise mode in which the solution of the arsenite of potassa is to be taken, they all agree that we should not carry it beyond fifteen, or at most, eighteen drops in the course of the day. I am in the habit of beginning with two minims of the solution, equal, in quantity, to 1-60th of a grain of arsenious acid, twice a-day, and to carry it up to five, six, or seven and a half minims, equal to the 1-18th of a grain of arsenious acid, three times a day; beyond which I believe it is never necessary to increase the dose, as I am convinced that the good effects of this remedy are to be obtained rather by small doses continued for a considerable time than by the exhibition of larger ones at longer intervals. But the smallest even of the quantities that have been mentioned are quite inadmissible, as will be shown in a subsequent part of this paper, in individuals of an excitable temperament.

Within the last two years another preparation of arsenic has been introduced to the notice of the profession, by Mr. Donovan, of Dublin, under the name of the "*Liquor Arsenici et Hydrargyri Iodidi*;" for a full account of the chemical composition and medicinal effects of which I may refer my readers to the papers by Mr. Donovan in the *Dublin Journal of Medical Science*. The dose of this preparation is variously stated. Dr. Kirby commences with doses of 20 minims, which he states are large enough to ensure the good effects of the remedy. Mr. Cusack recommends from 20 to 40 minims three times a day, which may, in some cases, be pushed to a greater extent. Dr. Irvine has given as much as half a drachm three times a day, for seventy-six days, with an intermission of only two or three days on account of headache and sickness. Dr. Graves ad-

ministered it to the extent of half a drachm four times a day for two months, with but two interruptions; and Sir Henry Marsh carried it, in the case of a boy twelve years of age, to the extent of half an ounce daily, in divided doses, which only produced very mild insalivation. Mr. Donovan is of opinion that it is prudent to begin with Dr. Kirby's doses; but he states that, after a time, a state of tolerance is induced, and then the medicine may be gradually increased at discretion. It has been administered to patients of all ages: thus, one of Sir H. Marsh's patients was but five years old, while both of Dr. Graves's had attained their sixtieth year, and Dr. Croker's her sixty-eighth. The composition of the liquor of the hydriodate of arsenic and mercury is, according to Mr. Donovan, as follows:—

Water, one drachm.

Arsenious acid, $\frac{1}{4}$ of a grain.

Peroxide of mercury, $\frac{1}{4}$ of a grain.

Iodine, as hydriodic acid, about $\frac{1}{4}$ of a gr.

Thus this preparation contains exactly a quarter as much arsenious acid as enters into the constitution of Fowler's solution, differing besides in other very obvious and important respects.

The iodide of arsenic, a very useful preparation of the metal, for the introduction of which into practice the profession is indebted to Dr. A. T. Thomson, is most conveniently administered in the form of pill. The dose of this preparation should not at first exceed the twelfth of a grain twice a day; this may gradually be increased until the patient takes the sixth, or even the fourth, of a grain three times a day, although these doses are very rarely necessary. The iodide of arsenic is most advantageously exhibited in combination with the extract of conium, which seems to sheathe its irritating qualities, and prevents it from exciting too powerfully the mucous membrane of the stomach. By the addition of biniodide of mercury a compound pill may be formed, which resembles, in its effects, the liquor of the hydriodate of arsenic and mercury, and has been much and successfully employed by Dr. A. T. Thomson in the treatment of lupus and other diseases of the skin, and which I have found of particular service in some syphilitic eruptions, more particularly of a squamous kind. Of its use in these affections I had an

interesting example last autumn, in the person of a country gentleman, the brother-in-law of a physician in this town, who had laboured under syphilitic psoriasis of the legs, the right one more particularly, for between five and six years; and who, in less than four weeks, got perfectly well under the use of a pill containing one-twelfth of a grain of the iodide of arsenic, one-sixth of a grain of the biniodide of mercury, and two grains of the extract of conium, twice a day; the iodide of arsenic being gradually increased to one-sixth of a grain, and the biniodide of mercury omitted, at the end of a fortnight, as it began to affect the gums. The diluted biniodide of mercury ointment was at the same time employed externally.

The arsenious acid, in an uncombined state, is but very seldom employed in this country, although with Bielt, and some other continental physicians, it is a favourite remedy in psoriasis inveterata, and other very obstinate cutaneous affections. Its dose, in the form of the "Asiatic pill," varies from the sixteenth up to the fourth of a grain twice a day. The comparatively large quantity of arsenious acid that is required in an uncombined state to produce a beneficial action on the skin, ought, in my opinion, to militate against its employment in this form. The minimum dose of arsenious acid recommended by most writers on the diseases of the skin is one-sixteenth of a grain; now this is equal to the quantity contained in seven and a half minims, almost the maximum dose, of the solution of the arsenite of potassa, and certainly too large a quantity of this preparation for us to be justified in commencing with. This difference in effect is probably owing to the greater readiness with which the arsenious acid, when presented in solution, must be taken up by any surface, and carried into the general circulation.

Mr. Donovan lays great stress upon the small quantity of arsenic, and of the other elements, that, in his preparation, sometimes effect a cure; but in this I do not think it presents any thing peculiar, or more remarkable, than is constantly seen in Fowler's solution, and the other preparations of arsenic. I shall have occasion, in another part of this paper, to relate the particulars of a case of hereditary confluent lichen, of many years' standing,

cured by less than a drachm of the solution of the arsenite of potassa, or not quite half a grain of arsenious acid, in the course of a month; and it is by no means very uncommon to meet with cases of disease of the skin that will get well with little more than half an ounce of Fowler's solution, or two grains of the arsenious acid, if the treatment be spread over a considerable space of time, and more particularly if the effects of the arsenical be aided by appropriate topical treatment, as the iodine and citrine ointments, the nitrate of silver, and poulticing, which appear to have been had recourse to in several cases reported in the Dublin Journal.

As my experience in the use of the liquor of the hydriodate of arsenic and mercury is as yet somewhat limited, not having been extended to more than six or seven cases, I do not at present feel myself justified in giving any opinion as to the comparative merits of this and of the other preparations of arsenic in the treatment of the diseases of the skin, although I may state that it has appeared to me to be of peculiar value in the treatment of the syphilitic affections, more especially those of a squamous character, in which cases the mercury very probably exercises a greater influence than the arsenic. I may mention a case that occurred to me a few months ago, in which it not only cured the cutaneous complaint under which the patient was labouring, but also removed rheumatic neuralgic pains of twenty-four years' standing; an effect which I have not seen attributed to it, but which it is probable that it shares in common with the other preparations of arsenic.

Lawrence Keane, *etat.* 46, an old sailor, of a sallow complexion, with dark hair and eyes, placed himself under my care on the 17th January last, for psoriasis of the posterior part of the neck and back, under which he had been labouring for the last four years. He states that, having been shipwrecked about twenty-four years ago, he was attacked with acute rheumatism, since which time he has never been free from pains in the limbs. I ordered him twenty minims of the solution of the hydriodate of arsenic and mercury three times a day, and a lotion of the bichloride of mercury to wash the affected parts with. On the 28th he had the dose of the solution

increased to thirty minims, and on the 15th of February he was perfectly cured of the disease of the skin, the rheumatic pains, from which he said he had not been free for twenty-four years, having ceased entirely for some time past. Since this date I have several times seen him, and he continues perfectly well in every respect.

That the liquor of the hydriodate of arsenic and mercury is a most useful preparation, and one that will prove a valuable addition to our materia medica, there can be no doubt; but I think that notwithstanding the very high encomiums that have been bestowed upon it by some of the first professional authorities in Great Britain, it yet remains to be proved whether it is superior to the other arsenical preparations already in use, except, perhaps, in some cases of the syphilitic eruptions, and of lupus, in which the mercury that enters into its composition might be expected to exercise a very decidedly beneficial influence; somewhat resembling, in this respect, the pills composed of the iodide of arsenic and the biniodide of mercury. The comparative value, however, of Donovan's solution, and of the other preparations of arsenic, is too important a question to be prejudged, and is one that can only be determined by actual observation; and as the remarks that I have to make in this paper have reference chiefly to the effect of arsenicals generally upon the diseases of the skin, I shall, for the present, omit its consideration.

The *modus operandi* of the arsenical preparations, as of most other medicinal agents, is unknown to us. We are only acquainted with their secondary effects, which manifest themselves most unequivocally on the digestive, nervous, and integumentary systems; on all of which they act as excitant or stimulating tonics. When arsenic is being given in medicinal doses, one of the earliest constitutional symptoms produced by it is an acceleration of the heart's action: this, as Dr. Duffin has remarked, and as I have had occasion to observe, sometimes becomes quickened in the course of a few days after the administration of the mineral has been commenced, by ten, twenty, and even thirty beats in the minute, the pulse acquiring at the same time a hard and somewhat wiry feel. This acceleration

of the pulse is particularly observable in individuals of sanguineous or sanguineo-nervous temperament, in whom the heart's action is readily excited under the influence of physical exertion, or of mental emotion. In some cases before, but in most after this increase in the rapidity of the heart's action, evidences of some degree of irritation about the mucous membrane of the stomach will manifest themselves; there will be more or less thirst; the tongue will become coated towards the centre and root, with red sides and tip; there will be loss of appetite and a sense of weight at the epigastrium; the patient, about the same time, will complain of heaviness and pricking sensations about the eyelids, with flashes of light before the eyes when they are closed, and after a time the eyelids will become puffed and droop, giving the countenance a peculiarly melancholy and care-worn appearance; there will also be more or less headache experienced, chiefly over the eye-brows and lower part of the forehead: this pain in the head is, indeed, very frequently, one of the first symptoms indicative of the medicine disagreeing with the system. The patient will also very commonly complain of confused and horrible dreams: this is more particularly the case with children, in whom, as the nervous system is very excitable, there is a natural tendency to irritation and disturbance of it. Girdlestone has remarked that in some cases the skin assumes a uniform lobster-red colour, that erysipelas comes on, or that phlyctenæ and pustules make their appearance when the arsenic disagrees. I have very frequently had occasion to observe that the disease of the skin for which the medicine may have been administered, more particularly if it be a case of chronic eczema, has evinced a decided tendency to increased action; the patches becoming red and irritable, showing that the integuments partake in the excitement that is induced in the system generally by the employment of these preparations. If the use of the arsenic be still persevered in, which, after one or more of the symptoms which have just been detailed have manifested themselves, should never under any circumstances be the case, we shall find that great irritation will supervene about the mucous membrane of the

stomach and throat; there will be nausea, vomiting, and total loss of appetite; the headache will increase in severity; the urine will become high-coloured; the countenance, which has become pale and sallow, will assume a remarkably sorrowful and anxious cast; tremors of the limbs come on, with an occasional feeling of faintness, and the foundation of incurable and permanent disease may be laid in the digestive organs or nervous system. It must not, however, be expected that all these symptoms should show themselves in every case in which the remedy has been pushed beyond its utmost limits as a medicine; far from it: in some instances the first symptom that we notice indicative of the medicine having begun to disagree, and of its employment having reached those bounds beyond which it cannot with safety be carried, is a degree of thirst, and a feeling of oppression about the epigastrium; in others, prickingsensations about the eyelids and flashes of light before the eyes; in others, again, and this very commonly, headache with disturbed dreams: and usually antecedent to, or, at all events, coincident with any one of these symptoms, will be found an acceleration in the pulse. The occurrence of any of these symptoms should be an instant warning to the practitioner to diminish the dose of the arsenic, or to intermit the use of the remedy altogether. If the patient be of a lymphatic temperament, or is somewhat advanced in years, of a languid debilitated habit of body, and the symptoms of excitement, local or general, be but trifling, it would be sufficient to diminish the dose to one half of that which is being taken, and to watch carefully the effects of the reduction before taking away the remainder. If, however, the patient be of a sanguine or sanguineo-nervous temperament, if he have been taking the arsenic for a considerable length of time, and if the symptoms of local disturbance be very unequivocal, it will be more prudent to leave off the use of the medicine for a few days, to give some saline aperient, and then, if it be thought expedient to do so, to recommence it in smaller doses. In practice it often becomes a question of considerable importance as to how far the preparations of arsenic may be carried; for this it is impossible to lay

down any fixed rule as to quantity or time, as these must necessarily vary very greatly in individual cases, and our only guide in these respects must be the symptoms of local or constitutional disturbance that they may occasion. From a careful examination of many cases of cutaneous disease in which this mineral had been employed, I am enabled to state that nothing is gained by carrying it beyond a certain point, as far as the affection of the skin is concerned, and that by so doing, much mischief, perhaps of an irremediable nature, may be inflicted on the patient; that it is not a remedy that can with safety be *pushed*, to use a common phrase, but that all the good that will result from its employment can be accomplished by a careful and guarded administration of it, and by its being intermitted on the first appearance of any symptom of local or general irritation. Any marked acceleration of the pulse, or disturbance in the functions of the stomach and nervous system, should serve as a warning to us to discontinue its use. It must also be borne in mind that arsenic is a cumulative remedy, and that its deleterious effects may suddenly be manifested at a time when we least expected it to disagree. On this account patients who are taking it should be seen by their medical attendant every second, or at most every third day, and should have directions given them to omit the medicine should any of the symptoms that have already been mentioned as indicative of its disagreeing with the habit, show themselves. In illustration of the bad effects that may result from the injudicious use of the preparations of arsenic, I may mention that I have at present under my observation a young lady, of a highly nervous temperament, but otherwise perfectly healthy, and without any hereditary disposition to disease, who whilst suffering from an attack of psoriasis of the legs some years ago, was advised to take Fowler's solution, which she did in the hope of speedily getting rid of, to a delicate female, a disgusting affection, to such an extent, without the knowledge, however, of the medical attendants, that she brought on extensive derangement of the stomach, which was followed by a violent neuralgic attack, together with, at a subsequent period, a distressing train of hysterical symptoms, which have ter-

minate. In a state of dementia, that, having now existed for nearly four years, may almost be looked upon as incurable.

Having thus briefly passed in review the symptoms that may be produced by the arsenical preparations—their doses—and those circumstances that indicate that their use has reached that point beyond which they cannot, consistently with the patient's safety, be carried, we shall pass to an investigation of those conditions, whether of the patient himself, or of the disease under which he is labouring, that indicate or contra-indicate their employment.

[To be continued.]

SYMPTOMS LIKE CROUP COMING ON AFTER SCARLET FEVER— TRACHEOTOMY.

To the Editor of the Medical Gazette.

SIR,

RICHARD M'CLAREN, 5 years and 10 months old, came under our care as a patient of the Ardwick and Ancoats Dispensary, 15th February, 1843, in a state of most laborious orthopnoea, threatening suffocation.

Three weeks before this he had been attacked with scarlet fever and sore throat; and upon the subsidence of the swelling and soreness of the throat he was seized with dyspnoea and croupy breathing, and croupy voice, having slept the night before in the workhouse upon boards covered with a blanket only.

We found him after this long suffering worn out with fatigue, for he had not slept for many days, so painfully laborious were the efforts to inspire; and his body was wasted to the last degree. His skin was dark, rough, dry, filthy, and encrusted all over with scales of ichthyosis; and the features as well as the limbs were furrowed and wrinkled, both from the effects of this cutaneous disease, and from his being emaciated almost to skin and bone. Added to these, the anxious expression of the countenance, and the painful agony of breathing, and the helpless debility of the poor boy, made him a distressing object to behold, and gave him something of an inhuman aspect.

His respirations were a continual gasping to get that breath which some

obstruction about the glottis prevented from entering freely, accompanied with a croupy noise on inspiring. Some voice remained, having a different tone from that of common croup, and distinct from that which attends the formation of false membrane. The pulse was small and quick, and extremely feeble, the surface of the body cool, and the lips pale and blue.

The agonizing need for breath; the debility, and the leanness of body; the advanced period of the disease, and its supervention on scarlet fever; the probable nature of the existing lesion, and the imminent danger of suffocation, all rendered the employment of the usual remedies inapplicable, and gave no hopes of their curative action, but rather reason to fear lest they should produce hurtful effects.

The history of the case, the particular succession of the morbid events, the nature of the local disease, and its confinement to the neighbourhood of the glottis, gave us great reason to hope for aid from tracheotomy—certainly, at least, for the relief of the agony, and probably also for the cure, by a successful operation. The whole circumstances of the case were singularly favourable for the operation, and the only reasons for apprehension arose from the ill-conditioned body of the boy, and the risk attendant upon some general indisposition of the economy.

The croup was sudden in its onset, and not preceded by catarrh of the lungs; and no symptoms or signs of pulmonary disease were discoverable. There was no dulness on percussion anywhere, nor irregularity of resonance over the chest; and these circumstances, together with the absence of catarrh, and of previous indications of pneumonia, as well as the general aspect of the patient, shewed that the complications of capillary bronchitis, and lobular as well as lobate inflammation of the lungs, were happily wanting.

The sudden onset of the croup with much violence, together with its long continuance in spite of the apparent severity of the attack; the great orthopnoea, with preponderating difficulty in the act of inspiring compared to that of expiration; the persistence of the croupy sound so late in the disease, and the voice remaining when suffocation was so imminent, and the

supervention of the attack upon the sore throat of scarlet fever, shewed that it was not an ordinary case of croup. The persistence of some distinctness of the voice is not commonly present at this late period of the malady, if the glottis and parts in its vicinity are clothed with false membrane.

The precedence of the sore throat of scarlet fever, under all those circumstances, afforded a strong presumption that the morbid lesion consisted in a swelling of the mucous membrane of the glottis and neighbouring structures, but complicated probably with the pigmy points of eroding ulcers, to which they are so liable in that fever. During the last mild epidemic of scarlatina we have seen some other cases in which the parts about the entrance of the windpipe were more or less affected in this manner. The inspection of the corpse of one child that died with symptoms of croup supervening on the fever, discovered no cause for death besides the extension of the swelling and ulcerous erosions from the fauces into the windpipe. Another, under the like circumstances, had some difficulty of breathing, which became suffocative whenever she cried or grew peevish; and those symptoms continued upwards of a fortnight, with complete extinction of the voice, before she manifested signs of amendment.

The two children spoken of, and the boy M'Claren, form three examples of different degrees of the same morbid state, which are worthy of notice. The one died from the utmost extension of the local disease, under circumstances in which tracheotomy would not have been proper. The other recovered without the same extension of the malady, and without absolute, but only after prospective danger, and without any need for the operation. The last was threatened with impending suffocation, when the disease had progressed too far for other treatment, and absolutely required surgical aid to restore the freedom of respiration, and to give a chance for recovery; and this was happily under circumstances, contrary to the first case, not only making tracheotomy prudent, but favourable to its success.

The scarlet fever had gone through its course, and the sore throat and tumor of the tonsils and neighbouring glands had disappeared. The swell-

ing of the mucous membrane, probably with ulcerous erosions, which had been promoted to the parts about the glottis by taking cold whilst the throat was yet sore, now remained alone, or only with some redness of the fauces. Thus the lesion of the mucous membrane was evidently progressing fast towards recovery; being serious only by reason of its extension to the narrow opening into the windpipe, and requiring only time to heal. No feverish symptoms obtained, and the local lesion was manifestly limited to a small space. Nothing seemed to foreshow any probability of the occurrence of dropsy; but the ichthyosis, perhaps, might have been a presumption to the contrary. The viscera of the belly and chest, and the functions of the brain, were proper in every respect. Lastly, the system had not been deranged by remedies.

Without a hope from medicines even for the relief of the agony, much less for saving the life of the child, we were of opinion, agreeably with our colleagues, that tracheotomy was needful and proper here, and offered the only means for the child's recovery.

Accordingly, after having obtained the consent of the mother and her friends, in the unavoidable absence of our colleague, Surgeon Harrison, on the 16th February Surgeon Dumville performed this operation in the most able manner, and with a degree of coolness and dexterity that does him great credit.

So completely had the poor boy been overcome with fatigue and sleeplessness and suffering, and so sudden was the relief obtained through the operation, that shortly after the insertion of the silver tube he fell fast asleep on the operating table, even before he was dressed or made comfortable. After the first moments of suspense, attending the relaxation of the spasm of the air-tubes, which arose from forcing the tube into the windpipe, he began to breathe with ease and freedom; and his ghastly features and his lips, which had a leaden hue before the operation, assumed their natural colour. He coughed up a little frothy mucus, mixed with blood, and quickly began to breathe with ease; and his respirations, which exceeded sixty in the minute for some hours after the operation, were only forty-eight next morning. On the evening of the third

day they were thirty-four; on the fourth, thirty-two; and on the eleventh, only twenty-seven; whilst from that period they varied in frequency, sometimes above, but mostly below, thirty in the minute.

The respiratory murmur, which was inaudible before, was heard after the operation throughout the lungs without morbid accompaniment. When the freedom of respiration was restored, the feeble pulse, barely perceptible before, rallied again in strength, numbering 132 strokes in the minute that night, but only 120 next morning, which standard it seldom exceeded afterwards during convalescence, but ranged lower to 115, 108, and sometimes as low as 102.

Early on the fourth morning the child passed a good feculent stool, and afterwards he had two or three evacuations daily upon an average.

The diet was most rigid for the first few days, namely, fresh cold water as a diluent, with bits of sugar to allay appetite; but so soon as no danger was to be feared from inflammatory action, we gave him nothing but the strongest drinks of animal juices and milk, and, lastly, solid meats. We abstained carefully from administering any medicines. The boy gradually acquired strength and flesh; and as the scales of the epidermis fell off, the functions of the skin were restored, and he attained progressively his wonted vigour of body; so that he plays about as roughly as others of his age, both in the house and abroad.

The operation has proved eminently successful; and the chief features of the case seem to be, first, the sequence of the croup upon the sore throat of scarlet fever; second, the absence of pulmonary complication; and third, the limited extent of the local malady.

The tube was removed first on the morning of the fourteenth day, but it became necessary to replace it again that same evening; and since then it has been taken out and cleaned three times. When the tube was out, and the opening into the windpipe closed with a sponge, then the boy spoke audibly, but with much hoarseness; and likewise, when he stops the hole of the tube with his finger, he can pronounce some words intelligibly, and he can sound a small whistle. The respiration through the glottis is not suffi-

ciently easy to justify the final attempt at present to do without the tube; nor is it quite free from croupy sibilus.

Let no one think that this is an operation of minor importance; on the contrary, perhaps no other requires nicer care for its success, or confers greater responsibility. The successful result we attribute, next to the dexterity of the operator, mainly to the unceasing care and watchfulness which we and our colleagues were enabled to bestow upon the case, the boy never having been without medical supervision an hour for upwards of two weeks. To our colleagues, Dr. Wilkinson and Surgeon Dumville, who partook with us in the responsibility of the case, and who shared equally in the watching by night and by day, we cannot sufficiently express how much we feel indebted; but those who know what the support of a good colleague is, where so much responsibility rests, can well appreciate our feeling.

We avoid purposely making any observations on the surgical bearings of the subject, leaving them to Surgeon Dumville, to whose province they especially belong, and who will, we hope, follow up our communication with some remarks on the practical matters relating to the operation, and the management of the apparatus, as well as with his own ingenious views upon other interesting features of the case.

Your humble servant,
THOMAS HODGSON WATTS, M.D.
Physician to the Ardwick and
Ancoats Dispensary.

53, Dale Street, Manchester,
April 12, 1843.

Surgeon Dumville's remarks in continuation of the preceding case.

In the case of the boy Richard M'Claren, tracheotomy was performed in preference to laryngotomy for the following reason—that, although we had evidence in proof that the lungs were not implicated in the disease sufficiently to justify us in resorting to an operation for the relief of the dyspnoea, yet we had no proof that the disease was wholly confined to the rima glottidis. It was therefore determined to make the section as low in the trachea as we could, in the expectation of making the wound in healthy structure.

An incision was made about two inches in length over the trachea,

avoiding the gland above, and not carried so far as to endanger the left subclavian vein. The edges of the sterno-thyroid muscles were carefully held apart by broad retractors. Two large thyroid veins were brought into view; and much difficulty was experienced at this point of the operation, for these veins adhered so closely to the trachea that it was no easy matter to remove them out of danger. As the thymus gland was large, and as the thyroid veins lay closely upon the trachea below, I thought it better to cut out a piece of one of the tracheal cartilages, sufficient to allow of the introduction of the large-sized canula that had been selected. I thought that there would be less risk of hæmorrhage by opening the trachea in this way than by making a longitudinal incision simply; and besides, I hoped that a more convenient aperture might be made for the introduction of the large tracheal pipe. There was, however, a little difficulty in inserting this tube, owing to the rapid manner in which the larynx rose and fell. As soon as the tube was fairly lodged, there was a free discharge of bloody mucus; the blood, I have no doubt, had been drawn in through the wound. Dr. Watts has already described the boy's appearance after the operation, and I will sum up in a few words. After the expulsion of the mucus, the respiration was performed with the greatest ease, and the contrast with the late dyspnoea was so strong that I thought the lad had ceased to breathe, when he was actually asleep.

I attribute the success of the operation mainly to the large size of the tube that was made use of, which, notwithstanding its ample calibre, required most assiduous attention to keep it pervious, and yet, after all, we were compelled four times to remove it, before we could detach the thick coating of hardened mucus which tenaciously adhered to its interior.

The experience I have had with this case convinces me not only of the necessity of employing a large pipe, but also of the propriety of disturbing it as little as possible when once inserted. However carefully it was taken out, and however adroitly it was replaced in the trachea, still the constitution suffered invariably for a time,

and in every instance there was much irritation set up in the throat.

The method we adopted for cleaning the tube was, first, to moisten the mucus adhering to the interior with a small sponge attached to a flexible silver wire, and then detaching the coating by means of a scoop bent to the shape of the pipe.

One circumstance has particularly arrested my attention in the surgical treatment of this case. It is this: that every time the tube has been taken out, although the boy could talk so as to be understood, yet the voice continued croupy, and the lad was incapable of breathing through the glottis with sufficient freedom to support life. In most cases of successful tracheotomy the result has been different; a few days have often been sufficient to allow of the subsidence of the laryngeal inflammation, so that the canula could be thenceforth removed. In the case before us the success is not so complete at present; but we are sanguine in our expectation of complete recovery, inasmuch as the lad's voice becomes gradually more free from croupy resonance.

Since Dr. Cheyne's Pathology of the Larynx and Bronchi appeared before the medical world, an opinion has been very generally prevalent that croup is under any circumstances an unfit case for operation. The unfitness consists in this, that the lining of the whole bronchial tube has been found frequently involved in the inflammation. This is undoubtedly correct in many, perhaps in the majority of cases, but certainly there are some instances in which the inflammation and false membrane are confined to the larynx. Dr. Howard showed me a preparation lately taken from one of his infirmity patients, a boy about six years old, in which the inflammation and false membrane had not extended into the trachea.

I will close these observations with a sketch of a case of croup which occurred in my practice last week.

Thomas Foden, æt. 2 years and 5 months, had been exposed for a long time to cold late in the evening of April 9th, but went to bed in perfect health. Next morning he rose with a slight cough and hoarseness, and towards the evening he experienced some difficulty in breathing. On

the second day he was much better. Also on the morning of the third day he appeared better; and although his hoarseness continued, still he could speak, and played about quite free from fever and having a good appetite, until about 3 o'clock P.M. when his dyspnoea and hoarseness grew rapidly worse, and he died early on the morning of the fourth day, 13th April. I only saw the little patient once.

Post-mortem.—The epiglottis was thick and inflamed; the glottis and the whole cavity of the larynx was lined with recent false membrane, and this false membrane extended but a very short way down the trachea, whilst a distinct line of demarcation distinguished the inflamed from the not inflamed structure. The trachea and bronchia contained some mucus; but the lungs were free from appearances of inflammatory disease. The preparation has been seen by many of my medical friends; and I am decidedly of opinion that bronchotomy might have been the means of saving this child's life. The freedom from fever was strong presumptive evidence that the lungs were free from inflammation.

I am, sir,

Your obedient servant,

ARTHUR WILLIAM DUMVILLE.

22, Higher Ardwick,
April 19, 1843.

CASE OF DIFFICULT PARTURITION.

To the Editor of the Medical Gazette.

SIR,

I TAKE leave to transmit to you the particulars of a case, which, though it occurred several years ago, you may nevertheless deem of sufficient interest to place on record in your *MEDICAL GAZETTE*. Time cannot deteriorate the value of facts so long as they point to practical usefulness, and a faithful relation of our own difficulties, and the mode by which they were overcome, may serve at least for some protection against the embarrassment, or difficulties, to which others are exposed.

In the night of the 13th March, 1811, Mr. Hopkinson, of Peterborough (since dead), a surgeon of acknowledged skill, and an accoucheur of great experience, being in attendance upon Mrs. — in labour, called me to his aid. On my

arrival he told me that the lady considered herself in the eighth month of utero-gestation, that the membranes had broke on the previous Sunday evening, without any pain, since which time she had not been sensible of the motion of the child, and though the head had descended into the vagina her pains had been of that distressing character which in the lying-in chamber are pronounced "wearing, yet of no avail." It may be mentioned that from the loss of her husband a few months previously, and various other afflicting circumstances, her spirits had suffered much depression, and her bodily health serious impairment. She had refused sustenance of every kind for several days; her stomach, indeed, had lost its retentive power; food even of the lightest quality, or tried in the most sparing manner, being always rejected. Her frame was naturally delicate, her person short, and the pelvis somewhat below the standard size. The face of the child presented, with the chin towards the pubes. When I was called to the patient she had no pains, and scarcely any pulse; accordingly we deemed it right, from the inert state of the uterus, as well as the exhaustion into which she had sunk, to attempt immediate delivery. Of the child's death, I may add, we had unquestionable proof, for, besides the patient's own conviction of the fact, as above hinted, the attendant factor was fully decisive of it: hence we were free to resolve on a mode of delivery with regard exclusively to the patient herself, and Mr. H. proposed to effect it by applying the blunt hook to the chin, and his finger to the mouth: if that method should fail it was determined to have recourse to the forceps. He succeeded at once, however, in extricating the head; but after delivering the shoulders, an obstacle, apparently unyielding and unconquerable, opposed any farther accomplishment of our object. Mr. Hopkinson gradually increased the force with which he tried to bring away the child, but to no purpose; and, after a considerable time spent in unavailing efforts, tempering force with prudence, he at length, to our dismay, extracted half the child, leaving the inferior half of the trunk, together with the extremities, in the womb. I applied my hand to the abdomen, which felt as much distended

as if it contained another child, besides the remains of the mutilated one. Mr. H. next introduced his hand into the uterus and secured two feet, which, from the immense bulk of the abdomen, he suspected to belong to another child. These with some difficulty he brought beyond the external parts, and included them in a ligature: but again the same impediment presented itself. Our efforts to obtain a hold of the thighs were fruitless, and at this stage of the delivery, in attempting to draw down, I separated one of the legs of the child from its attachments above. Our next alternative was again to introduce the hand high up, which, when attempted by Mr. Hopkinson, he felt obstructed by a tense substance or tumor, lodged at the brim of the pelvis. This he succeeded in rupturing, and an enormous discharge of fluid was the immediate result. The great obstacle being at length overcome, instead of another child, the remnant or mutilated half was instantly brought away, and the uterus, except of its placenta, emptied. Syncope immediately followed the delivery, but from this our patient rallied, and the stomach fortunately retaining the wine and nourishment we gave, I rejoice to say she progressively and permanently did well.

The tumor occupied the lower region of the back, was constituted of watery cysts, and their aggregate bulk at the time was compared to that of a full-sized adult cranium. Thus, what we considered in the first instance an evil greatly to be deplored, proved in the issue an advantage, since with such a tumor it was utterly impossible to deliver the child entire; or, unruptured, to accomplish delivery at all.

I cannot conclude without noticing the formidable effects of pressure in this case—pressure of the gravid uterus on the subjacent or neighbouring viscera. I have already instanced the distressing sickness which the patient suffered: constipation proved another bane of equal obstinacy: despite of aperient medicines and clysters she passed the whole week antecedent to her delivery without the slightest alvine discharge: the bladder had lost its power of expulsion: moreover, the pains she suffered from the distension and weight of the uterus (pains, it may be remarked, by no means simulating those of labour), were woefully

distressing; so urgent, indeed, as to induce Mr. H. to give a drachm of Tinctura Opii every three hours for some continuance.

This, sir, is a plain unvarnished statement of a case which, I am aware, is not of very frequent occurrence. Tumor of a child's abdomen, as well as of the back, may impede the process of delivery by its lodgment at the brim of the pelvis; and nothing, it is manifest, in either case, but the puncture or rupture of such a tumor, will insure the life of the mother, the chief and great object of the obstetric art. In fine, my desire is to call attention not so much to that which is rare as that which is useful, and with this assurance permit me to subscribe myself, sir,

Your obedient servant,

J. WHITSED.

Wisbeach, April 28, 1843.

ON THE
DIFFERENCE OF THE BILE AS IT
FLOWS FROM THE LIVER, AND
THE CYSTIC BILE.

By GEORGE KEMP, M.D. Cantab.

—
To the Editor of the Medical Gazette.

SIR,

IN the course of my researches on the bile, it became necessary to examine the nature of the secretion as immediately given off from the liver, before its entrance into the gall-bladder. It was desirable to ascertain, in fact, whether any essential difference exists between the fluid as it flows from the liver, and the cystic bile; and it was hoped that, by establishing the exact relation which subsists between the two, we might obtain a more accurate knowledge of the real nature of this important body.

The only written authority which has afforded me any assistance on the subject is the Physiology of Professor Müller, which contains the following sentence. "The bile which flows from the liver is of a lighter colour; that obtained from the gall-bladder is less fluid and greener, on account of the more fluid part having been absorbed, and it is more viscid, owing to its containing mucus." Now we must infer from this that the opinion of Professor

Müller is, that the two fluids only differ from each other in the diminished quantity of water, and in the presence of mucus in the cystic bile. This is also the opinion generally received. The following results of actual experiment will I hope be considered worthy of perusal, as they differ so essentially from what we should have presumed *a priori*, and as adding one more example of the necessity of extreme caution in this interesting department of research.

The whole of the liver of an ox, with its gall-bladder attached, was obtained immediately on its removal from the animal; the gall-bladder was carefully separated, and the liver placed under a jet of water to remove the secretion from the larger hepatic ducts. The organ was then cut into small slices and placed in about a quart of distilled water for some hours, the object of this process being to obtain the fluid contained in the smaller branches of the ducts. Having strained the whole through cloth, a fluid was obtained strongly coloured with blood, and containing, of course, a large quantity of uncoagulated albumen. The fluid was now boiled for an hour, and again strained through cloth, and the resulting liquid submitted to examination. No reaction was produced on turmeric paper; it *was totally destitute of the peculiarly bitter taste* so characteristic of cystic bile, though highly charged with yellow colouring matter. The smell was nauseous, not unlike a solution of glue, but not in the slightest degree resembling that of the bile as usually found in the gall-bladder. After carefully evaporating the fluid to dryness, it was heated with alcohol, sp. gr. 340, by which the yellow colouring matter, and a substance (A), was dissolved. The residue (B), was very carefully washed with alcohol, and a portion burned on the platinum knife. I thought that this residue was the mucus of the hepatic ducts, and expected to obtain an ash of phosphate of lime; the result, however, was carbonate of soda. It will be remembered that the aqueous solution of this body was neutral; it is therefore an electro-negative body in combination with soda. The alcoholic solution, also neutral, was now evaporated to dryness, and a portion of the substance (A), burned on platinum; again I obtained carbonate

of soda. Each of these bodies, therefore, is principally composed of an electro-negative body in combination with soda; until, however, the ultimate analysis is made, it cannot be decided in what relation these bodies stand to the electro-negative body in the cystic bile, but I hope shortly to forward you their elementary composition.

It would seem, then, from the above, that the bile of the *ox*, at least, undergoes a remarkable change in the gall-bladder; and it seems highly probable that what has been usually denominated the *mucus* of the gall-bladder is an important agent in effecting the change. An interesting point now to be investigated is, under what condition does the bile present itself in animals which have no gall-bladder? Indeed, to make the subject at all complete, it will be necessary to commence a general research into the nature of the bile given off from the liver in animals of essentially different habits and structure.

Will you permit me, in conclusion, through the medium of your pages, to solicit the attention of the profession to one point, which has, I believe, now been clearly made out. The cystic bile, when fresh, and in a perfectly healthy state, is always neutral; at least this is the result of many more than a hundred cases which I have examined, including the ox, the human bile, the bile from several species of monkey*, the tiger, the wolf*, the dog, the cat, the fox, an Indian bull*, and various kinds of fish, so that this property may fairly be presumed to be a distinctive mark of healthy bile in graminivorous, carnivorous, and omnivorous animals.

I have only met with three exceptions to this remark: the first was in the case of a child which had died from a severe burn; the second was that of an Indian bull, in which the bile was so putrid that it was unfit for particular examination; and the third was in an ox, the biliary ducts of which were completely choked up with an insect (*Distoma hepatica*).

It would be but a very trifling sacrifice of time in our large hospitals to examine the bile of every person submitted to a *post-mortem* examination

* The bile of the animals marked (*) was obtained through the kindness of Dr. Clark, Professor of Anatomy in this University.

with turmeric paper*, and I should esteem it a great favour to receive any addition to my tables on this subject by post.—I remain, sir,

Your obedient servant,

GEORGE KEMP, M.D. Cantab.

St. Peter's College, Cambridge,

A CASE OF
STRANGULATED FEMORAL
HERNIA,

IN WHICH THE SAC WAS DISTENDED WITH
FLUID BLOOD.

By J. TOYNBEE, Esq. F.R.S.

Surgeon to the St. George's and St. James's
Dispensary.

(For the Medical Gazette.)

As it is important to place on record every variety presented by so interesting a disease as hernia, I take the opportunity of publishing the following case, which displayed some peculiarities worthy of notice.

Mrs. H., æt. 50, tall and thin, and who had been losing flesh for six months, was seized with a pain in the right groin whilst exerting herself in the middle of the day of February 28th. The pain was very acute for some time, but it gradually disappeared. Towards evening the usual symptoms of strangulated hernia presented themselves, and on retiring to bed a swelling was perceived in the right groin, which was rather augmented on the following morning. During the early part of the day of February 29th, the patient walked about the house: at 2 o'clock the pain and sickness had considerably increased, and she suddenly fainted, when my attendance was requested. Upon examination I found a tumor in the right groin, of the size of a small hen's egg, produced by a femoral hernia; it was remarkably hard and incompressible, and its size was not at all diminished by the application of the taxis. An operation was therefore determined upon, which I performed the same evening, with the kind assistance of my colleague, Mr. Chapman. Nothing unusual presented itself in the steps of the operation until the hernial sac was exposed; it was of the size of

a small walnut, very tense, and perfectly black. Upon laying it open, it was found to owe a great part of its size to the presence within it of a large quantity of dark-coloured blood, of the consistence of treacle. At its upper part was a small rounded mass, also quite black, and irregular to the touch. Several coatings of firm fibrine were removed from its surface, and in its centre a very small portion of omentum was exposed, having a dark colour but possessing its natural consistence. Upon a careful examination, finding there was no oozing of blood from its surface, I divided the stricture at Poupart's ligament, and returned the protruded part into the abdominal cavity. No unfavourable symptoms supervened. The patient was quite recovered in three weeks, and has remained well to the present period. The peculiarities in this case, dependent upon the presence of thick fluid blood in the hernial sac, and of the layers of fibrine coating the omentum, are likely to afford some embarrassment to an operator who meets with them for the first time, without being aware of the probability of their existence.

12, Argyll Place, St. James's,
April 26th, 1843.

INDIAN HEMP.

To the Editor of the Medical Gazette.

SIR,

As the observations of Dr. O'Shaughnessy on the remarkable effects produced in India by the extract of *cannabis*, or common hemp, have disposed many gentlemen to make trial of its powers in this country, may I request you to give your readers the following caution.

The *apocynum cannabinum* is sold in London under the name of "Indian hemp." It is a native of Canada and Virginia, and has no resemblance to the true hemp, except in possessing a tough fibrous bark, which is applicable to the same purposes in the arts. In the U. S. Pharmacopœia it is termed "Indian Hemp." The officinal part is the root, which is powerfully emetic and cathartic. But the part which I have seen supplied as Indian hemp consists of the leaves and the follicles filled with numerous silky seeds. As the follicles are 2 to 3 inches long, and

* After testing the fluid it is always desirable to wash the test-paper with distilled water, as the colouring matter of the bile is otherwise apt to mislead.

the silky seeds are abundant, they can hardly have escaped the notice of those who may have inadvertently used this article under the idea that it was the hemp from India. The true Indian hemp, or "gunjat," is our common hemp; and consists of the flowering branches, two or three feet long, nearly destitute of leaves, and having the flowers and fruit (hemp-seed) agglutinated together by the resinous secretion. As the most powerful antispasmodic properties have been attributed to this plant, it is important that no false conclusions should be drawn in consequence of the employment of a wrong article. I am not aware that any real Indian hemp is at present in this country except the supply recently brought by Dr. O'Shaughnessy, and left with Mr. Squire, of Oxford Street. We have at present little experience of the medicinal properties of English hemp. A hotter climate, a more intense light, and a different soil, may give to it properties which are scarcely developed in this country, but as the resinous secretion is not wanting here, it appears deserving of a careful trial.

I am, sir,

Your obedient servant,

T. J. FARRE, M.D.

Curzon Street, May 1, 1843.

MEDICAL GAZETTE.

Friday, May 5, 1843.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

QUACK MEDICINES.

To suppose the extinction of quackery is almost to presuppose the arrival of the millennium; for we must either imagine disease to have disappeared from the world, or the art of medicine to have obtained such miraculous perfection that the most impatient patient could never be driven by despair to consult the quack instead of the physician. Yet it is possible to imagine that, with another century or so of education and discussion, something

short of this, yet something very good, will have been attained; and that, in four or five generations, a belief in the wonder-working powers of quack medicines will rank with a belief in witchcraft, and be found only in remote districts and among uninstructed persons. Till the arrival of this happy era, we must put our trust in reasoning, and in diffusing a knowledge of the powers of medicines and of the structure and functions of the human body; for medical dissent can no more be quelled by prosecutions and prohibitions than theological speculations can be permanently crushed by thumbscrews and Conventicle Acts.

The analogy may be carried further; for though, in every unenslaved country, freedom implies discussion, and discussion necessarily produces dissent, still overmuch dissent is a reproach to the creed of the majority: and thus a deluge of quackery implies something rotten in the profession which it supersedes. It shows that legitimate practitioners err in theory or in practice. Either they cannot explain the principles on which they act, or they cannot cure *tutò, celeriter, et jucundè*; or, perchance, they take a leaf from their adversaries' book, and copy the errors against which they declaim.

An explanation of this subject from time to time, for the benefit of the laity, must do good; and we are, therefore, pleased to find it discussed in a temperate and rational manner by Dr. T. G. Wright. His essay was lately read before the Mechanics' Institute at Wakefield, and has since appeared in the shape of a pamphlet.

A great part of it consists in a commentary on some popular errors.

Thus, it is commonly fancied that illness assumes a certain number of unalterable forms, as well defined as the provinces of a nicely-coloured map; here jaundice all yellow, and there

apoplexy all red; in this corner Dropsy displaying his bloated belly, and in that one Mania shaking her iron chain. The smallest disease that takes rank in our nosologies is supposed to be distinct and immutable; he that runs may read them; and to confound one with another would argue the most culpable blindness! Moreover, it is thought by the *ignobile vulgus* of various ranks, that each skilful practitioner has a choice selection of remedies, good for particular diseases, and that doctor differs from doctor chiefly in the rare disposition of this ideal medicine-chest.

Diagnosis, in short, goes for nothing in vulgar estimation, and remedies for every thing. Hence it is supposed that one practitioner can transmit or even sell his skill to another; and hence, too, family recipes good for the gout, dropsy, or what not, are handed down from one generation to another, in sober, steady, mistaken families.

We cannot agree, however, with Dr. Wright, in confounding the doctrine of the empirics of old with medicine as practised by modern quacks or *dilettanti*. The empirics, though rejecting the theories on which medicine had been based, adopted all the refinements of treatment which had been sanctioned by experience; while the blunderers whom Dr. Wright castigates merely prescribe for a score or two of diseases, or rather of names.

We cannot allow my Lady Bountiful to suppose that she belongs to the ancient and honoured sect of empirics, though she may be an empiric in the modern sense.

The old sect consisted of educated men, to whom the registers of medicine were open, and who profited by the mistakes, as well as by the discoveries, of their predecessors; the modern one is made up of blunderers, unwilling, or unable, to be taught either by the living or the dead. Independently of

this, the extremes of refinement and of coarseness make a decided practical difference between the old and the new school, and destroy the historical defence of the latter; just as a man who attempts to open a vein with an oyster-knife cannot fairly allege in his defence that it is a cutting instrument as much as a lancet.

Again, it is a popular error to attribute too much to causes inherent in the constitution of the patient, and too little to external agents. Much is said of the biliousness of his temperament, and little of the causes which have made and keep him so. In other words, Hygiene, the best and safest portion of medicine, is little regarded by the common people, and forms no part of the quack-medicine system.

Another mistake, and a very frequent one, is to confound the symptom with the disease, and to suppose that two similar aches or uncomfortable states must necessarily be relieved by the same remedy. How can they, if they arise from totally different causes? Can the headaches of Congerro, who is an alderman, and of Irus, who inhabits a Union Workhouse, require the same treatment? Assuredly not. Yet we must believe this, if we believe the advertisements of the infallible Maltese elixir. Perhaps, however, the most extravagant of all the opinions current on this subject is the belief that many or any quacks have discovered drugs good for this or that distemper. This is unquestionably the wildest of all the fictions touching nostrums with which the public is bewildered. Your cold and calculating quack may select some well-known combination of medicines, provide it with a stamp, and puff it as a panacea for every mortal ill; but as for imagining such a fellow to be among the honourable band of discoverers, one might as well imagine a caricaturist rivalling Michael Angelo.

Many of the remedies which are advertised are external applications, and it would be a good beginning, in the instruction of the laity, to teach them what can be done medicinally in the shape of salve or unguent. The surgeon can stimulate, or soothe, or simply protect an ulcerated surface; but the healing herbs of the old romances have vanished and left no successors.

A very signal triumph of nostrums over common sense, consists, no doubt, in universal specifics, in which, as Dr. Wright says, "the mighty genius of quackery delights to revel." Every Friday, it seems, the market of Wakefield is visited by a pillmonger of the comprehensive class, who cries out, "In any case whatsoever, no matter what the case may be, if you are afflicted, only take my medicine and you are *sure* to be cured!"

Now, what is the cause of all this? What is the reason that quackery is so much more prevalent in medicine than in any other art? The reason is a simple one, and though we have stated it before, it will bear telling again. The reason, then, is, that nature is to a certain extent the support of the charlatan; and while a quack or imaginary engineer could not make even a bad railway, the medical quack, or imaginary doctor, will not always prevent the disease from getting well. Nature cures fevers, but makes no tunnels. Again, although it is a sad thing to be reduced by poverty or by folly to take drugs at random, yet it is by no means the case that random shots miss every time. This is especially true of purgatives. Hence we think that Dr. Wright has overstated his case in one respect. He supposes a prescription for some common aperient pills to be taken from a physician's table, and the medicine to be administered indiscriminately to five thousand patients; and he thinks it not improbable that

three or four, or even ten or twenty, might be considerably benefited by them. Only twenty! we should have put down a thousand as much nearer the mark. Could the *Pil. Rhei C.* hit the mark only four times in a thousand? Nay, we really think that the chance of benefit to be obtained out of any respectable medicine taken by accident, from Aconitum to Zingiber, must be represented by a larger fraction than $\frac{20}{1000}$.

But boundless fame is within the reach of these same *Pil. Rhei C.*, disguised, peradventure, under the name of the Bala Hissar pills, the recipe for which was found, as the advertisement might affirm, "in the baggage of an Affghan chief!"

"It may be," says Dr. Wright, "that a not-very-clever medical man has been previously consulted, or that one of greater repute has been misled in the case; and if so, there is no end to the glory of the fortunate pills."

Hence it appears that the quack-salver has two advantages of which it would be difficult to deprive him. The one is, that he is patronized by nature, who in the cure of disease backs every thing, and every body; the other is, that medicines given blindfold must sometimes do good, especially if they are purgatives. Nevertheless, the final though distant extinction of quackery is to be hoped for; it forms a fragment of that final triumph of reason and virtue which is the secret consolation of every philanthropist.

DR. LATHAM.

(For the Medical Gazette.)

LAST week we noticed the death of Dr. Latham, senior, in his 82d year. He was the father of the College of Physicians. None of his immediate contemporaries are now alive, and his juniors by ten years are almost all past away. He had himself long retired from the world, so that of the

physicians now in active practice few could have known him. Yet he was eminent in his time, and enjoyed a large share of the esteem and confidence of mankind.

Half a century ago there were three physicians of St. Bartholomew's Hospital, who, each in succession and each early in life, and unaided except by their own strenuous industry and talent, ran a rapid career of success. These were, Dr. David Pitcairn, Dr. Austin, and Dr. Latham. The fortunes of all three were peculiar and instructive.

Dr. Austin, in the midst of great business and the brightest prospects, was cut off by a fever at the age of forty.

Dr. Pitcairn, between 40 and 50, had his prosperity arrested by hæmoptysis, and retired to Lisbon in search of health. He returned to a less practice but an undiminished reputation, and died about his 60th year from acute inflammation of the larynx.

Dr. Latham, at the age of 46, was worn out by the hard labour of his early success. He was believed to be consumptive, and retired into the country (it was thought) to die. But he recovered, and returned to town, and resumed the exercise of his profession. He felt, however, that, if he was to keep the health he had regained, he must never again put it to the same hazard.

Accordingly he now removed far away from the sphere of his former business. He left Bedford Row, and settled in Harley Street. And here, for twenty years, he enjoyed, with a more moderate practice, a larger share of health than he had known during the days of his greater labour and greater success.

In the year 1814, Dr. Latham was elected President of the College. In 1816, he founded the Medical Benevolent Society. He contributed several papers on practical subjects to the Medical Transactions. In 1809, he wrote a small volume entitled, "Facts and Opinions concerning Diabetes."

In 1829, having reached his 68th year, Dr. Latham finally left London. Fourteen years of life yet remained to him. For two-thirds of this period he enjoyed the comforts which are still within the reach of a vigorous old age. For the last third was reserved the sharpest of all bodily afflictions, the formation and gradual increase of stone

in the bladder. Under this he sank, and died.

The fame of physicians, except of the few in any age who have pushed forward the boundaries of physiological and pathological knowledge, does not outlive the recollection of those who knew them, or have derived benefit from their skill and care. Those who knew Dr. Latham, both his patients and his fellow physicians, speak of him with great esteem and affection. His patients remember the confidence and encouragement which accompanied his address, his sincerity, his straightforwardness, and his liberality: and there are physicians, now grey-headed, who speak of the kindness and countenance they received from him in the days of their youth.

But the highest virtues of good men are unseen by the world while they live; and are kept sacred for the solace and contemplation of their families when they die. More, therefore, need not be said of Dr. Latham, except that he was singularly temperate, when temperance was hardly yet thought to be a virtue; he was most pure in life and conversation, when to have been otherwise would have provoked no censure; and he was not ashamed to be religious, when religion had yet no recommendation or countenance from the world.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

April 35, 1813.

THE PRESIDENT IN THE CHAIR.

Cases of Strangulated Hernia reduced en masse, with observations. By J. LUKK, Esq. Surgeon to the London and St. Luke's Hospitals; and Lecturer on Surgery. [Communicated by Sir B. C. BRODIE, Bart.]

In this paper the object of the author is to show that the reduction of a strangulated hernia *en masse*, although rare, is not so infrequent as is generally supposed; and that the occurrence should be considered as coming within the ordinary range of probabilities of surgical practice. He had seen five cases of this description, two of which had been subject to his own treatment. In these the hernial tumor had been reduced entirely, through the parietes, into the abdominal cavity, with the contents strangulated; and as no swelling was perceptible, while the usual symptoms of strangulation continued, the diagnosis was rendered extremely obscure. The author gives the details of the two cases.

which occurred in his own practice; and describes minutely the steps of the operation which he performed in each. In one case, owing to the deceptive nature of the symptoms, and absence of external tumor, the operation was deferred too long, and the patient died. On examination, the hernial sac was found to occupy a considerable space just within the abdominal parietes, in the vicinity of the internal ring; the fundus lay a little below its level, towards the cavity of the pelvis; while the neck, still contracted, so as obviously to have been the original seat of stricture, was between three and four inches distant from the situation of the ring, and lay in an upward direction towards the umbilicus. The whole sphacelated contents were empty, collapsed, and in a pulpy state. In the second case, the result of the operation was successful. In describing its stages, the author mentions that before the hernial sac could be reached it was necessary to lay open the inguinal canal by dividing the tendon of the external oblique muscle. Near the external ring the spermatic cord was seen lying bare, or only covered with a little fat. It was only when the finger was passed through the internal ring (the firm borders of which were distinctly perceptible), and pressed a little more deeply within the abdomen, that a round tense tumor could be felt, which was found to be the hernial sac. The internal ring was cut through, and this allowed the sac to be drawn downwards; when it was opened, the stricture divided, and the bowel returned into the abdomen. The author concludes his paper by adding observations on the propriety, in doubtful cases of strangulated hernia, of performing an exploring operation to ascertain the exact nature of the case. He points out, at considerable length, the various conditions of the parts in the inguinal canal, from which, when taken along with the history of the case, the surgeon may judge whether the hernial sac, with the bowel strangulated within it, has been forced into the abdominal cavity, and expresses his opinion that such an operation will not involve the patient in much additional danger.

FELLOWES' CLINICAL PRIZE REPORTS.

BY ALFRED J. TAPSON.

University College Hospital, 1842.

[Continued from p. 104.]

CASE X.—*Splenitis (?) coming on after intermittent fever; with rheumatism and signs of incipient phthisis. The splenitis cured by leeches, blistering, and mercury, &c.*

EDWARD MORGAN, æt. 23, admitted May 6, 1842, under Dr. A. T. Thomson. A man

of moderately stout conformation and sanguine temperament; complexion naturally florid, but since his illness has been much paler, and rather sallow; parents both living and both healthy, as well as eight brothers and sisters; is single, and of regular sober habits; is a sailor, and has made several voyages to India, Australia, &c. as steward.

His health was always good till December 1841, when he was returning from the East Indies; at this time he was seized with headache, feverishness, burning pains in various parts, diarrhoea, &c. and after these symptoms had lasted about three days a severe attack of quotidian ague came on; the paroxysms coming on in the evening with violent shivering, &c. and ending on the following morning with sweating. The ague lasted for eight or ten weeks altogether, but during the last three or four weeks the paroxysms were irregular in their occurrence, coming on every third or fourth day, and the intervals gradually lengthened till the paroxysms ceased to recur. In February he reached St. Helena, and was then subjected to a regular course of mercury, and severely salivated, and since that time he has never had a regular fit of ague. During the whole attack he had suffered most from pain in the left hypochondriac region; it was diminished after the salivation, but has never left him entirely; the salivation was attended with great swelling of the face, and he continued to spit a great deal for two or three weeks, after which time he gradually regained his strength and resumed his work. In the beginning of April he was much exposed to cold and wet, owing to rough weather, and he was attacked with pain in various parts of his body, especially in the knees and ankles, attended with swelling, redness, &c. and at the same time there appeared a number of dark red or purple spots on the shin-bones, and afterwards small hard swellings; the gums were swollen and bled on the least touch; the urine was very high coloured, and on three occasions it resembled blood, and his mouth now swelled again. He landed on the 29th of April, and for a few days seemed better, but on the third he walked about a great deal, and on the fourth the pain in the side became greatly increased; the legs swelled, and the rheumatic pains in the limbs returned, and he was brought to the hospital to-day (May 6th) with the following symptoms.

The surface of the body generally is warm and moist; face pale, rather sallow, and has somewhat an anxious expression; the gums are spongy, and the teeth, he says, are loose; tongue clean. He complains of a severe stabbing pain in the left hypochondriac region, extending forward to the umbilicus and backwards towards the spine, much increased by pressure and by lying on the

right side; in the latter position there is a dragging sensation in addition to the sharp pain above, it is also worse after taking food; he feels most easy when lying on the back inclined to the left side; he also has pains in the knees, ankles, shins, &c.; the ankles are slightly swollen, and pit on pressure; has had a slight cough for the last two or three weeks, with expectoration of mucus; pulse 84, small, not resisting; bowels regular; urine rather pale; sp. gr. 1009; reaction acid, not albuminous.

Physical signs.—Percussion rather dull under the right clavicle and in the right supra-scapular fossa, as compared with the same parts on the left side; and in the same situations the respiration is bronchial, and bronchophony is heard. The sounds and impulse of the heart are natural, and there is no morbid sound. The dulness in the left hypochondrium, in the region of the spleen, is considerably extended, reaching from about an inch and a half below the left nipple almost down to the left groin—a distance of eight inches. It reaches forwards nearly to the umbilicus, and backwards to within about three inches of the spine.

Admoveantur Hirud. xij. parti dolenti lateris.

R. Calomel. ; Antim. Potassio-Tart. ; Opii, singulorum, gr. vj. M. ft. pil. vj. Sumatur una 8vâ quâque horâ.

R. Potass. Nitrât. gr. xv. ; Mist. Camph. f3iss. ft. haust. inter sing. dos. pilul. sumendus. Low diet.

8th.—The leeches alleviated the pain in the side almost as soon as they had been applied; it is now much easier, and there is less tenderness on pressure.

9th.—He now feels the pain at times only, and then not severe. He can lie on the right side without increasing pain. The extent of dulness in the side is much the same, except that it does not seem to extend quite so far forward. Looks and feels more comfortable. The pains in the limbs are easier, and the œdema of the ankles is almost gone; cough less; pulse natural; bowels open; urine increased in quantity; natural in colour; sp. gr. 1016; not albuminous.

10th.—No pain in the side now; has an aching pain in the epigastrium, and bowels rather confined.

R. Haust. purgans niger q. p. sumendus.

Pergat in usu pil. et Haust. Salin.

Applicetur Emplast. Cantharid. parti dolenti, et curetur pars vesicata Unguento Hydrargyri.

12th.—The size of the spleen, as ascertained by percussion, is greatly diminished; it only reaches now to about three inches below the left nipple, and its extent is di-

minished in other directions also. No pains in the limbs; feels rather weak. The mouth is sore, gums tender, some salivation, and the mercurial foetor is perceptible. Bowels open. Urine rather scanty; sp. gr. 1012, clear, not albuminous.

Sumatur pilula nocte maneque vice ter die.

14th.—Quite free from pain; the side is quite raw from the mercurial ointment, mouth very tender, and salivation pretty considerable; urine plentiful; reaction acid; sp. gr. 1010; clear; rendered cloudy by heat and nitric acid; and on standing a precipitate of albumen falls.

Sumatur pilula omni nocte tantum.

16th.—The face is swelled considerably, especially the left side of it. The tongue is also swelled, rendering articulation indistinct. The discharge of saliva is abundant, and there is a little blood mixed with it, apparently coming from the gums; bowels open; urine very turbid, and deposits a very copious pinkish sediment of the lithates; sp. gr. 1027; reaction strongly acid, not albuminous.

Omitt. pilulæ et Ung. Hydrarg. Dress the side with water-dressing.

R. Liq. Plumb. Diacet. f3iss. ; Aquæ, f3vij. ft. gargarisma sæpe utend.

17th.—Swelling less on the left side of the face, and the tongue also is less swelled; it has a blackish crust on it, and some of this matter, which probably is altered blood, is mixed with the saliva.

Sumatur Haust. Salin. 6tà qq. horâ.

R. Liq. Plumb. Diacet. f3j. ; Sp. Vini Rectif. f3iij. ; Aquæ, f3vij. M. ft. lotio pro ore subinde utenda.

19th.—The swelling very much less, and also the salivation: the pain and tenderness are completely gone from the left side, and he can bear firm percussion without pain being felt. The dulness is much less extensive, reaching only up to the 8th rib, so that there is a clear space of more than three inches below the nipple. In other directions also the dulness is diminished, but less so. Urine very turbid, with a pinkish sediment, soluble in ammonia or liq. potassæ, or by heat. The addition of an equal volume of nitric acid to some of the urine causes the formation of a number of crystals of nitrate of urea on cooling.

23d.—Face and tongue nearly natural in size, and salivation very trifling; gums rather pale, and tongue looks spongy, and is pitted on the margin; has no pain anywhere; can lie on either side without inconvenience; bowels regular; urine plentiful and natural.

Physical signs much the same as on the 6th instant. The expiration is loud and

prolonged in the same situations as the bronchial respiration and bronchophony. The left side of the abdomen feels much softer, and more flaccid. The dulness on percussion commences a little more than three inches below the left nipple, and extends downwards about five inches, and its transverse extent is about the same.

R. Potass. Liquoris, *℥xxiv.*; Infusi Quassie, *℥jss.* ft. haustus bis indies sumendus. Omitt. Haust. Salin. Milk diet, and a mutton chop daily.

26th.—Countenance much more natural; cheeks gaining a little red tinge; is gaining strength daily; appetite good; pulse natural; no pain anywhere; bowels regular; urine abundant and natural.

28th.—Going on very well; recovering fast. Has no pain in the side; but if firm pressure be made about three inches to the left of the umbilicus there is a little tenderness felt.

Full diet and chop daily.

30th.—Is much stronger; can walk pretty well; the dulness of the spleen reaches to the level of the umbilicus, and the lower end of it can be distinctly felt here; it is very slightly tender on its inner side, but this is scarcely worth noticing. The size seems to vary a little at different times, sometimes being rather larger than at others.

Discharged cured.

REMARKS.—Inflammation of the spleen is by no means a common disease, and, indeed, its existence is doubted by some, whilst, on the other hand, some have gone so far as to describe two varieties, one affecting the capsule, the other the proper substance of the spleen. The existence of inflammation of the capsule, independently of the substance of the spleen, may fairly be questioned, considering the multitude of processes which are given off by it, and distributed throughout the interior of the organ, and most intimately connected with the proper substance of the spleen; and even did it exist, there would be no special signs by which we could distinguish it from a local inflammation of the partial peritoneal investment of the spleen; and, indeed, it is so closely united to this membrane, that we can scarcely conceive that it could occur without exciting peritonitis. If the substance of the spleen were not affected there would be no perceptible enlargement; and as there was, in this case, we may leave this point.

In the case now under our notice the symptoms were a sharp lancinating pain in the left hypochondriac region, much increased by pressure externally—by taking food which would cause the stomach to press against the spleen, and also by lying on the right side, in which position the

spleen, from its increased size and weight, produced a dragging sensation, as though there had been a weight hanging from the left side. The size of the spleen was ascertained by percussion to be very greatly enlarged, the dulness being at least twice as extensive as it is in health.

From these symptoms the existence of splenitis was assumed; but it may be argued, by those who deny this disease, that these signs may exist without there being splenitis; and therefore, as morbid anatomy has thrown very little light on diseases of the spleen, is it not better to attribute the signs to any other cause that might produce them rather than to splenitis? Thus, in this case, granting that the spleen had become enlarged during the attack of intermittent fever, would not the addition of local peritonitis account for all the other symptoms? It no doubt would account for the pain in the side, increased by pressure or by lying on the right side. The character of the pain also was such as is usual in inflammations of serous membranes, viz. sharp and lancinating; and the very fact of the greatly increased size of the spleen would tend to confirm the view, as this would act as a cause of peritonitis by stretching the peritoneum.

It seems to us most probable that the acute symptoms depended on peritonitis, produced either by the influence of fatigue and cold, on a part predisposed to inflammation from the stretching and traction resulting from the enlargement of the spleen, or else by the aggravation and extension of a chronic inflammation of the spleen, which, in the latter case, must be assumed to have been the cause of the enlargement, and of the pain which had been felt during, and ever since, the attack of intermittent fever. Hitherto it has not been shewn what is the pathological nature of these enlargements of the spleen; but it is certain, from the very rapid effects of some remedies, especially quinine, in reducing the size, that part of the increased size is due to congestion: whether there is, besides this, a chronic inflammation we cannot be certain: the influence of mercury, in the present case, in diminishing the size, as it is known to do in chronic inflammation of other organs, seems to countenance the idea that it (inflammation) did exist; but we can come to no certain conclusion on this point.

In addition to the preceding signs of disease of the spleen, there were other symptoms which would, by some persons, in accordance with their views of the functions of the spleen, be referred to the derangement of the functions consequent on its morbid condition, viz. the pale sallow complexion, the slightly yellow tinge of the conjunctivæ, the œdema of the ankles, and the

symptoms of scurvy and purpura as noticed in the history; all of these clearly shewed a morbid state of the blood, but it by no means is to be deduced that this depended on the condition of the spleen; it is at least equally as philosophical to regard the condition of the spleen and that of the blood as results of a common cause, viz. malaria.

These were the chief things for which he came to the hospital; but he had besides rheumatic pains in the limbs—the remains of an attack of rheumatism a few weeks before he was admitted—and he had also some symptoms of incipient phthisis, viz. slight hacking cough, and mucous expectoration, together with the physical signs of condensation of the upper portion of the right lung: thus, there was dulness on percussion under the right clavicle, and in the right supra-scapular fossa, as compared with the left side, and in both these situations bronchial respiration, and strong bronchophony. The condensation thus indicated probably arose from tuberculous deposition; it was just in that condition in which the disease may lie dormant for many years, and it seems likely that it may do so in this case, as before he left the hospital the cough had entirely ceased, and there was not a single symptom referrible to the lungs.

Next, as regards the treatment. The symptoms of local inflammation indicated the abstraction of blood, but not to any great extent, as there was scarcely any general fever: the application of leeches to the seat of the pain was therefore deemed sufficient, and we have seen that this was followed by almost instantaneous relief. He was also ordered calomel, with opium, and tartar emetic, to be continued till the system was brought under the influence of the mercury, and nitrate of potash was added to act as a diuretic to remove the oedema and to improve the condition of the blood. Three days after this a blister was applied to the side, and the blistered surface dressed with mercurial ointment until a considerable amount of salivation was produced.

Under this treatment all the symptoms gave way, both of the affection of the spleen and of the rheumatism; his appetite returned and also his strength; the sallowness disappeared from his countenance and eyes, and the red colour began to return to his face. No other means of any importance were used; he was, for a few days before he was discharged, given a tonic mixture and extra full diet, and went out quite well on the 30th of May, a little more than three weeks from the date of his admission, during which time he had lost all symptoms of disease of the spleen, except perhaps slight enlargement and very slight tenderness at one point on firm pressure.

It is clear from the above case that mer-

cury is very useful in enlargement of the spleen with inflammation, notwithstanding that it is said by some to be injurious.

The urine underwent a considerable number of changes in the progress of the case: the only changes we shall here refer to are, the great abundance of the lithates, and the appearance of albumen in the urine for a single day (May 14th), just at the time the salivation commenced. We attribute this to the influence of the mercury, as we have seen it in several other cases under precisely similar circumstances, viz. just at the time the gums became sore, and in each case lasting only for one day. What the nature of the action of mercury in producing this may be, we cannot tell; it may be that it diminishes the cohesions of the solids, as it is stated to do by Dieterich, and thus allows the transudation of the serum of the blood through the capillaries of the kidneys, or it may produce some change in the composition of the blood; and perhaps this is the beneficial *modus operandi* of mercury in inflammation, producing a state the reverse of that produced by the disease, and thus counteracting it; but neither of these will explain why the albumen has only been found (in these cases) for a single day. The prognosis, from the age, previous good health, &c. was favourable as to the result, but so speedy a cure could hardly have been anticipated.

[We may notice that he came back to the hospital for a few minutes on 23rd June, having been in the country ever since he left the hospital: he had gained much flesh and colour, and seemed quite well.]

MEDICAL REFORM.

ANNUAL GENERAL MEETING OF THE NORTH OF ENGLAND MEDICAL ASSOCIATION.

THE members of this influential body held their anniversary meeting on Wednesday last, in the lecture-room of the Athenæum, Fawcett-street, Sunderland,—Dr. HEADLAM, President of the Association, in the chair,

Mr. C. T. Carter, of Newcastle, the Secretary of the Association, read the following REPORT:—

A period of nearly three years and a half has now elapsed since the formation of this Society; and during that period, five Reports have been submitted to general meetings. In presenting a sixth, the Council have the gratification to announce the unabated prosperity of the Association during the past year. Notwithstanding the great distance at which many of its members reside from the more immediate scene of its transactions, the little opportunity they must of necessity enjoy, from one anniversary meeting to another, of learning the nature of its pro-

ceedings, and the difficulty (in some cases the impossibility) they must experience in attending those meetings, it is satisfactory to find that they continue to yield their support to the several objects for which it was instituted, evincing thereby a degree of zeal on behalf of their common profession well deserving of applause and imitation.

The first and foremost of these objects has ever been, to assist in procuring such a legislative reorganization of the profession as shall be adapted to the circumstances in which it is at present placed—not only in reference to its own members, but to the interests of the community at large. In the pursuit of this object, the hopes of the medical body have been alternately flattered and disappointed; and it has been the duty of your Council to report, from time to time, the failure of every attempt which has been made, within the last few years, to legislate upon this difficult and complicated subject. Under these circumstances, it is not surprising that some gentlemen, who joined this Society in the sanguine expectation that the unsatisfactory state of medical affairs was to be rectified at once, should have become disheartened, and that, despairing of success, or doubtful at least of the utility of their individual aid, they should have deserted the ranks of the Association. But it is satisfactory to know, that if some have withdrawn themselves, there have been others ready to supply their places, and that, in spite of every discouragement, the Association has steadily kept its ground. Some who stood aloof at its formation, either from misapprehension or mistrust of its designs, have, now that time has been allowed for their development, enrolled themselves amongst its members—considering properly, that although the assistance of any one man may avail but little in the correction of evils and abuses, it should nevertheless be added to the general effort. And this, in fact, is all that is required: let the number of those who are willing to aid the cause of professional amendment, by never so little, be converted from hundreds into thousands, and that cause must, at no distant period, be crowned with abundant success. Let no one give way to despondency on account of the delay which *must* take place before the arrival of this period. Impediments and hindrances should serve but to exercise patience, and excite to renewed exertions.

Your Council deem it unnecessary to dilate on the good results which are likely to ensue from Associations such as this. It is impossible that such bodies should not exert a considerable moral influence both upon the profession and the public. Upon the former they are calculated to produce effects which cannot fail to secure the increased respect and consideration of the latter; and

it should never be forgotten, that the interests and well-being of each are inseparably connected, and that the medical body can seek no improvement of its own condition, which would not be productive of beneficial consequences to every class and grade of the community. Members of the profession should not be disappointed if the progress of improvement be slow and almost imperceptible. The ordinary avocations of medical men are of an engrossing character, and are liable to interfere with that frequent intercourse which is requisite to the carrying out of any concerted scheme or line of action in affairs not immediately connected with the practice of their art. Your Council have to regret, that, from this circumstance, it has been found difficult to give to many topics of interest that full and careful consideration to which they are entitled; and in resigning their functions, they would take the liberty of suggesting to their successors to consider, whether, by the appointment of Committees on individual subjects, or by some other means, this disadvantage may not in future be obviated, or at least materially diminished. The inconvenience of frequently bringing together members of this Association, scattered as they are over three extensive counties, induced the Council, some time ago, to recommend, and the Association to resolve, that, except for special and extraordinary purposes, there should be but one general meeting in the year. This arrangement was accompanied by a strong recommendation in favour of sectional subdivisions and meetings, as a means of fulfilling more particularly some of the second class of objects contemplated by the association. Such local unions might be rendered useful in a variety of ways, which will readily occur to every mind; as in promoting harmony and community of feeling—in cherishing a due observance of professional honour and etiquette, in discussing and arranging matters of mutual interests, in affording mutual protection, and, in towns where there is no Society established for that purpose, in advancing medical literature and science.

In reference to medical legislation, the last year has been one of expectancy rather than of action. The profession has been awaiting the introduction into Parliament of the Bill announced by Sir James Graham in the early part of last session. From the peculiar nature of his office, it has been considered that on no one could the responsibility of such a measure rest with so much propriety as on Her Majesty's Secretary of State for the Home Department, and that in no hands could the carrying of a Medical Bill through Parliament be so certain of success. It has been imagined, moreover, that in undertaking a task of so much complexity, and involving so many interests,

both public and professional, the Minister would feel it his duty to avail himself of all those sources of information which are peculiarly open to the Home Office ; that in deliberating on this momentous question, the *general good* would be the paramount consideration.

Your Council regret, that although two separate applications have been made for the purpose, they are unable to submit to this meeting any official outline of the anticipated Bill of Sir James Graham. From what they have been enabled to glean of its contents, they are induced to believe that its provisions are, or were, not widely different from those which, upon surmise, they ventured to criticize in their last Report ; and it is needless to say, that if such be the case, the Bill, how acceptable soever it may prove to certain parties in the profession, cannot fail, in several most important particulars, to disappoint a great numerical majority of its members. Your Council by no means wish to affirm that some parts of the Bill, as reported, would not be productive of good, nor constitute improvements on the present system. If rightly informed, it would tend to promote an incorporation of the physicians of each country, and a uniform standard of qualification for medical degrees. Upon the justice and propriety of such an arrangement the opinion of this Association has been repeatedly expressed ; and it is gratifying to know, that a growing inclination in its favour has of late years been exhibited by most of the Universities and Medical Colleges of the United Kingdom. As a natural consequence of uniformity in the conditions attached to the granting of medical degrees, the restrictions which have hitherto prevailed with regard to the right of practising in particular districts would be removed ; the power now held by the Royal College of Physicians of London to examine for its license the graduates of British Universities would be withdrawn, along with most of those questionable parts of its constitution which have entailed upon the College so much unpopularity, and occasioned so many undignified conflicts between the different classes of its members. The executive bodies of the Colleges of Physicians, it is also supposed, would be no longer self-elected, but chosen by their respective commonalties—the latter being made to comprehend all the legally recognized physicians of each country. The Colleges would thus serve as Courts of Record for Medical Degrees, and their registers would probably be the means of detecting and exposing parties who should usurp the title of M. D., or hold it merely in virtue of a purchased continental diploma.

The Bill, it has been supposed, would also

tend to promote something like uniformity in the education in the general practitioner, and would enforce a double qualification on all who should hereafter receive a license to practise as members of that branch of the profession. Such an arrangement is not only expedient but necessary. There is at present no greater evil in the profession than that arising from the unfair competition caused by the dissimilarity of qualification which prevails among general practitioners, and in consequence of which it happens, that while some parties, in order to qualify themselves for general practice, incur the labour and expense of completing the separate curricula of study, and submitting themselves to the separate examinations required for the diploma of the College of Surgeons and the license of the Society of Apothecaries, there are others, acting in a similar capacity, who have subjected themselves to the ordeal of *one only* of these Boards—an injustice which will be instantly apparent, when it is remembered, that the former body institutes no inquiry into the *medical* knowledge of candidates for its diploma, while the latter takes no cognizance of *surgery* in the course of study and examinations which precede the granting of its license.

It is said that the Bill of Sir James Graham would require all future English general practitioners to be examined in some departments of medical science by the College of Surgeons. The hall of the Apothecaries' Company would be no longer the scene of medical examinations. Some of its members would, however, assist in the examinations at the College of Physicians, and the license of the Company would be taken as heretofore by the general practitioner. This arrangement appears to your Council to be one of the most objectionable parts of the Bill, and would almost serve to indicate the parties by whose advice its right honourable framer would seem to have been actuated in its construction. If the general practitioner is to be no longer examined by the Company of Apothecaries, why should he continue to receive his license from that Company ? If his examination is to be conducted jointly by the Colleges of Physicians and Surgeons, under such regulations as should be approved of by a General Board or Council, why should not his license be granted by that board ?

It might have been imagined that in legislating anew for the medical profession an opportunity would have been taken to rectify the error committed by the London Colleges in the year 1815, and to atone for their supercilious disregard of that numerous and useful body of practitioners, whom they, in that year, consigned to the

care and keeping of a "City Guild and Trading Company of Apothecaries."*

Your Council do not mean to assert that the Apothecaries' Company has not endeavoured faithfully to discharge the functions which, through the supineness of the Colleges, and even in opposition to its own wishes, it has been called on to fulfil. On the contrary, they willingly admit that much success has attended its exertions. The gradually increased amount of qualification now required of the general practitioner is unquestionably to be attributed to the Apothecaries' Company. Not unmindful, therefore, of its services, and with no feeling of disrespect, the Council are yet of opinion that the control of medical education, and the licensing of medical men, should never have been entrusted to this Corporation, and that, under a proper sense of duty on the part of the Colleges of Physicians and Surgeons, and a right understanding of the case by the Legislature, such an office would not have devolved upon the Society of Apothecaries. They are persuaded, that in consideration of his acquirements, and the position at present occupied by the general practitioner, both in society and the public confidence, he should cease to bear the stamp of an *apothecary*; he should no longer be identified with a functionary now all but obsolete: his authority to practise the *profession* of Medicine should no more emanate from a *trading* Company.

It is affirmed that a new order, to be entitled "*Fellows of the Royal College of Surgeons*," is to be created, which your Council suppose will consist chiefly or entirely of that class of practitioners who may be desirous to limit their practice more particularly to the surgical branch of the healing art. The "*Fellows*," it is believed, are intended to constitute the electoral body of the College, while the *members* or general practitioners will have no voice in the election of its officers, or in the management of collegiate affairs. From the Councils of the Colleges of Physicians and Surgeons of the three countries are to be chosen the medical members of a Central or General Medical Council, to which is to be confided the superintendence and control of the entire profession. As to the propriety of a General Council there can be no question. Its efficiency, and the respect in which it shall be held by the public and the profession, must of course depend in a great measure on the materials of which it may be composed. If the foregoing surmises be correct, the Council will be little else than an offset of the Metropolitan Colleges; and as the mass of practitioners has been systematically dis-

regarded hitherto, so now, according to the reputed Bill, would they be excluded from all control or influence over the medical polity of the United Kingdom. Coincident with the latter circumstance, the principle of *protection*, clearly recognized by the Apothecaries' Act, but which, from the inappropriate and defective character of the details of that measure, has been too feebly acted upon to suppress a small amount even of the unauthorized practice for which this country is notorious amongst the civilized nations of the world—this principle, it appears, would be exchanged for a species of negative restriction, or, in other words, a *discouragement* of unqualified pretenders to medical knowledge and surgical skill—a discouragement which your Council have reason to believe, and which an adequate acquaintance with the actual state of medical practice throughout the land, especially in rural districts, can hardly fail to demonstrate, would oppose but a feeble barrier to the cruel, dangerous, and fraudulent practices of ignorance, cupidity, and imposture.

Members of this association are probably aware that towards the close of the last session of Parliament Sir James Graham said it was in contemplation to propose the immediate granting of new Charters to the Colleges of Physicians and Surgeons of London, and the subsequent introduction into Parliament of a Bill for the regulation of the medical profession in general. Your Council, thinking that the granting of such Charters would prejudice the general question, petitioned both Houses of Parliament that they would not sanction such a proceeding, but withhold their support from any Charter until the whole subject of medical affairs should be brought before them. The Council took steps for insuring the presentation of similar petitions from Newcastle, Gateshead, Durham, Carlisle, Sunderland, North and South Shields, Berwick, &c., copies of petitions having been transcribed and sent for signature to those places. Members of Parliament were urged at the same time to support their prayer. After the lapse of a few days, Sir James Graham, in reply to a question put to him by Mr. D. Barclay, M.P. for Sunderland, declared that he had abandoned the idea of proposing the Charters during the session of 1842. Medical legislation having thus been once more postponed, and your Council, in reply to a recent application, having been informed that the Bill of the Home Secretary was not sufficiently matured to admit of an *outline* being submitted to their inspection, it is sincerely hoped that the interval may have been employed in framing a measure more suited to the exigencies both of the public and the profession than the

* J. H. Green.

reported Bill of 1842 could have been capable of supplying. The proper regulation of the medical profession is a matter of vital importance to society at large: its interest is not limited to medical men alone, as is too commonly supposed; and on this account it is most earnestly to be wished that any measure having reference thereto may be carefully and attentively considered, and with a view, not to favour the designs of any particular party or institution, but to benefit the whole community. It is a question involving the safety and comfort, not of the living only, but of millions of yet unborn subjects of the British empire and its vast dependencies; and the statesman who shall be instrumental in placing this important branch of national polity on a proper basis will have thereby earned for himself the admiration and gratitude of his country.

It would be a work of supererogation to revert, on the present occasion, to the principles of medical reform which have been advocated by this Association, seeing that they have been so frequently explained in five preceding Reports. It is a source of gratification to your Council, that those principles should have been steadily gaining ground, and that they should be identical, or nearly so, with the opinions promulgated by some of the ablest men who have directed their attention to the subject. They have been supported by the estimable Professor of Medicine in the University of Oxford (Dr. Kidd), and by the late venerated Professor of Anatomy in the University of Dublin (Dr. Macartney.) They have been urged, through a long and honourable career, by Dr. Barlow, of Bath. They have been enforced by Dr. Thomson, late Professor of Pathology in the University of Edinburgh—by Sir James Clark, Mr. Carmichael of Dublin, Dr. Marshall Hall, Dr. G. Webster, Dr. Forbes, Dr. Grant, Mr. R. D. Grainger, and many others, among whom it is but just to mention the name of one of the Vice-Presidents of this Association, Mr. Greenhow. Without wishing to make invidious distinctions where praise is due to all, your Council cannot refrain from expressing the great pleasure they have derived from a perusal of the letters addressed to Sir James Graham by Sir James Clark. To this eminent physician the thanks of the profession are justly due for his able advocacy. Occupying a foremost rank in his own department of practice, Sir James Clark has boldly stepped forward to advocate the improvement and amelioration of the *whole* professional body; and while he maintains the expediency of divisions of medical labour (which few indeed, if any, have denied), and the persistence of the distinctions and grades already recognized in the profession, he claims for *all* practi-

tioners a good and sufficient education, both preliminary and professional, an equal legal recognition of *all*, and the enrolment of *all* in "one great corporate institution." Sir James Clark is of opinion that there should be but one prescribed course of medical education exacted by the State; that it should comprehend what is necessary for every medical practitioner, and should be the same throughout the empire. They who would prognosticate from such an arrangement the annihilation of prevailing divisions, distinctions, and honorary titles, may derive some alleviation of their fears from the following extract:—"Whatever department of the profession," observes Sir James, "the medical man may choose as the field of his practice, to practise that part properly he must be acquainted with the whole. When possessed of such general knowledge of his profession, the practitioner may, by devoting his attention to one department chiefly, be fairly supposed to excel, and generally will excel, the man who practises them all. Thus one man, by directing his principal attention to the investigation and treatment of diseases affecting internal organs and the general system—another, by directing his chief attention to the diseases and injuries of the external organs, and the operations and mechanical appliances required for their cure—may each attain, in their respective departments, a degree of perfection which cannot be expected of him whose attention is divided among the whole range of human infirmities and accidents. Hence there will always be physicians and surgeons, who, in addition to their individual practice, will be consulted by the general practitioner in dangerous and obscure diseases." The regulations respecting honorary degrees in medicine, the writer thinks, may be safely left to the Universities and Colleges. "Much," says he in continuation, "has been said of the necessity of requiring high literary and scientific attainments of physicians, in order to secure their high standing and character with the public. Any law for this purpose is quite unnecessary. Insist upon the general practitioner being well instructed, and you at once insure a still higher education for the physician."

Your Council beg to recommend the letters of Sir James Clark to the notice of all who are interested in the subject of medical education or medical government. They trust, moreover, that his example, and that of the other eminent individuals already named, will stimulate the profession to exert itself at the present critical moment; and as a Bill may be possibly introduced during the present session of Parliament, no time should be lost in making known its opinions and wishes to the Legislature, through the medium of petitions. They are glad to per-

ceive the activity which has lately been displayed by the practitioners of Surrey, Worcestershire, Liverpool, and Chichester, and would beg to suggest the propriety of meetings being convened for the purpose of petitioning both in the counties and towns of the United Kingdom. Your Council have prepared a petition, which they take the liberty to submit to this meeting; and, if approved, they trust that others of a similar kind will be forwarded from the several towns comprised within the district of this Association. They hope the profession will not rest satisfied with the mere act of petitioning, but that each of its members will feel that something more than this devolves upon him *individually*. There must be few indeed who cannot exert *some* degree of influence, both with members of the Legislature and the public; and it must never be forgotten that the progress of amendment has hitherto had to contend with no obstacle so great as the apathy and indifference of a large portion of the medical body itself.

After the length to which the preceding observations have been extended, your Council are unwilling to detain this meeting with a recapitulation of the several subjects to which, in addition to the all-absorbing one of legislative reform, their attention has been directed during the past twelvemonth. Some of these require no comment, whilst others may be said to remain *sub judice*, and might perhaps, with advantage, afford scope for inquiry by the Council which will be elected to-day. The Report on Hospital Appointments, read at the last anniversary meeting, has occasioned much discussion at different periods during the year, but nothing need be said respecting it in this place, as the Committee has of late resumed its sittings, and is prepared to submit a second Report to the meeting.

Mr. Carter, having concluded the Report, proceeded to read a statement of accounts. It was a subject of congratulation, he observed, that the Association was in a prosperous financial condition. At their former meeting in Sunderland, two years ago, they were £16 in debt. Last year, they had a balance in hand of £2. 7s. 6½d., which was increased in the present year to £30. 1s. 0½d. (applause), in addition to £40 due from members in arrear.

Dr. Brown moved that the report be received, printed, and circulated.

The motion was put and carried, and the Secretary read the following petition to parliament:—

To the Honourable the Commons of the United Kingdom of Great Britain and Ireland, in Parliament assembled.

The petition of the President, Vice-Presidents, and Members of the North of Eng-

land Medical Association, in Public Meeting convened, at Sunderland, this 26th day of April, 1843,

Humbly sheweth,—That your petitioners (consisting of physicians and surgeons resident in the counties of Durham, Northumberland, and Cumberland,) have long deplored the defective and anomalous state of the medical profession in Great Britain and Ireland.

That your petitioners, having reason to believe that measures have been for some time in contemplation for reorganising and reforming the profession, beg respectfully but earnestly to impress upon your Honourable House the great importance of this question to the community at large, and its consequently strong claims to an early adjustment.

That your petitioners, having paid much attention to the subject, take the liberty of stating their persuasion, that any measure of Medical Reform, to be permanently beneficial, must provide for the union and consolidation of the whole professional body, and the proper qualification of all persons who shall hereafter be legally authorized to practise the healing art within Her Majesty's dominions. Your petitioners are further of opinion that uniformity in the qualification for a license to practise should be enforced; that honorary degrees in Medicine and Surgery should be conferred on a uniform principle; that reciprocal privileges should be enjoyed by the medical practitioners of England, Scotland, and Ireland; and that suitable measures should be adopted for protecting the public from the dangerous and fatal consequences of unauthorized medical and surgical practice.

Your petitioners therefore pray that the present state of the medical profession may receive the early attention of your Honourable House.

And your petitioners, as in duty bound, will ever pray.

Signed for and on behalf of the Meeting,

T. E. HEADLAM, M.D. President.

CHARLES T. CARTER, Secretary.

On the motion of Dr. Knott, of Newcastle, seconded by Mr. Watson, of Sunderland, it was resolved, that Mr. David Barclay be requested to present it to the House of Commons; also, that a similar petition be presented to the House of Lords, and that the Marquis of Londonderry be requested to take charge of its presentation.

After some further discussion on various points, for which we cannot make room, the thanks of the meeting were voted to Dr. Headlam for his conduct in the chair; and in the evening the members dined together at the Bridge Hotel.

NATURE AND TREATMENT OF APOPLEXY.

I PROPOSE to prove that there is no such disease as sanguineous apoplexy, and that bleeding is always prejudicial in the treatment of apoplexy. Here, I travel without a guide ; no author has yet professed this doctrine ; happy shall I be if, in explaining it according to my view, and as it has been revealed to me at the bedside of the patient, I succeed in eradicating a dangerous error which has been introduced into the healing art, and in enriching it with a novel truth.

Let us examine the dead bodies of patients who have died of apoplexy ; and beginning with the brain, in which M. Portal believes the cause of death from apoplexy is always seated, Morgagni assures us, from his own dissections and those of Varoli, that the brain of apoplectics does not contain a larger quantity of excremental parts than that of other dead boodies.

Morgagni, who does not generally make use of repetition, repeats this assertion several times in his writings. It is strange that M. Portal should not have seen it ; if he have read it, it is still more astonishing that he should have thought himself authorised to overturn a doctrine universally received, because he has found certain diseased appearances in the *brain* of one apoplectic patient.

Morgagni appears to have foreseen and condemned beforehand the system of M. Portal, when he says : “ I do not agree with those who, when they find water in the cranium of an apoplectic, think immediately that it has caused the disease.”

“ It is the common error,” says Lancisi, “ of those who have no experience : when they find lymph in the cavities of the brain, they are in the habit of attributing the apoplexy to it as the cause, whilst commonly it is only the effect.”

With respect to the water which is found in the cranium of apoplectics, Morgagni adds : “ You are aware that authors assert that the ventricles of the brain always contain a little water, in the natural state ; besides you see very clearly that the quantity of water cannot be greater than in hydrocephalus internus ; and yet Vesalius states that he has found in a child two years old, affected with this disease, about nine pints of water ; he adds, that the child preserved its senses to the last moment ; that it had, it is true, extreme weakness in the limbs, but that they were not paralysed. Besides this,” continues Morgagni, “ you well know, from a number of dissections described by Bonnet, in his work, entitled *Le Cimetière anatomique*, that tumors have been found in the cranium which had not been followed by apoplexy. But I have myself seen, as I have before noticed in my *journal*, an anormal increase of bony sub-

stance in those bones of the cranium, which presented a considerable protuberance inwards and compressed the brain, without this compression having produced either apoplexy or any other disease.”

“ I opened,” says M. Thiéry, “ fifteen bodies of persons from sixty to ninety years of age. The vessels of the head were very full ; four times I found polypous concretions in the longitudinal and lateral sinuses ; in others the ventricles of the brain were filled with serum ; such are exactly the appearances I have met with, in the same proportion, in persons destroyed by apoplexy : these, however, had died without the slightest appearance of apoplexy. On the other hand, I have opened many bodies of persons who died suddenly from apoplexy, either on the third or fourth day after the attack, and have found only slight congestion of the vessels, without extravasation of any kind.”

Sauvages says, that, “ when water is found in the sinuses of the brain, it is not therefore to be said that this serosity has been the cause of the apoplexy. I have seen hydrocephalus to an enormous extent without apoplexy ; several authors have made the same observation.”

I think it unnecessary to notice every kind of extravasation that may take place in the cranium, since the statement of Morgagni, the result of numerous dissections, embraces all the disorders which the brain presents ; and he asserts that they ought never to be considered as causes of apoplexy, whilst they are met with indifferently in patients who have died from apoplexy, and in those who have died from any other cause.

I shall observe, however, that extravasation of blood would prove the existence of sanguineous apoplexy less than extravasation of serum.

If the globules of the blood had as much tenuity, and were as fluid as the serous part, would not they escape with the latter, when it escapes ? This is self-evident. If, then, the globules remain in the vessels, whilst the serum is extravasated, they remain there only on account of their greater consistence and greater thickness ; now this consistence and thickness of the blood are allied to the state which is called *inflammatory*. Sanguineous apoplexy, which is supposed to arise from this pretended inflammatory thickening of the blood, cannot therefore present the extravasation of blood spoken of, since its density opposes it ; it is sufficient therefore to see blood extravasated in the brain, to be certain that, if that extravasation is anything else than the effect of the disease, it does not, at all events, prove the existence of sanguineous apoplexy.

* From Mr. Copeman's translation of Jean Antoine Gay's Essay on the Nature and Treatment of Apoplexy—lately published.

ON THE SIGNS OF DEATH.

DR. DESCHAMPS, of Melun, has presented to the French Academy of Medicine a memoir on the real sign of death. He draws the following conclusions, intended to guide public authorities in the precautions that should be taken against the danger of interring prematurely persons not really dead.

The author has observed that, in warm-blooded vertebratæ, putrefaction proceeds from the circumference towards the centre, and contrariwise in the cold-blooded; and he arrives at the following conclusions.

1. A greenish blue colour, extending uniformly over the skin of the belly, is the real and certain sign of death.

2. The period at which this sign appears varies much; but it takes place in about three days under favourable circumstances of warmth and moisture.

3. Though discolouration of various kinds, and from various causes, may occur in other parts, the characteristic mark of death is to be found only in the belly.

4. Apparent death can no longer be confounded with real death; the belly never being coloured green or blue in any case of the former.

5. This colouring of the belly, which may be artificially hastened, entirely prevents the danger of premature interment.

6. There is no danger to public health from the keeping a body until the appearance of the characteristic sign of death.—*Gazette Medicale*, April 1.

BIRMINGHAM HOSPITAL.

MR. JUKES has resigned the office of surgeon to the Birmingham Hospital, which he long held with so much credit. He has been succeeded by Mr. Crompton, who was elected on Friday, the 29th ultimo.

COLLEGE OF PHYSICIANS.

AT a Board held at the Royal College of Physicians, on Saturday the 28th ult. Sir Henry Hallford, Bart., President; the following gentlemen were examined, and obtained their degrees in medicine: Mr. W. T. Ballantine, Surgeon, Royal Navy; Mr. T. Sale, Surgeon, Isle of Man; Mr. S. Newington, A.B. Oxford; Mr. G. Moor., Hastings; Mr. W. Major, Hungerford, Berks; Mr. Tomkils, Yeovil.

ROYAL COLLEGE OF SURGEONS.

LIST OF GENTLEMEN ADMITTED MEMBERS.

Friday, April 28, 1843.

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE XXVI.

*On protracted and difficult labours from
anchylosis of the coccyx and tumors
within the pelvis.*

Anchylosis of the coccyx.

THIS is not a common cause of protracted and difficult labour. No distinct case of tedious labour from this disease has come under my observation. Dr. F. Ramsbotham states that he has seen three cases in which the bone broke, or the anchylosed joint gave way, but there is no detailed account given by him of the duration of the labours, or of the manner in which they terminated. Dr. Haslewood, of Darlington, met with a case of severe and protracted labour, in which the forehead of the child rested on the point of the sacrum and coccyx for many hours, and the head was indented by the sharp point of the coccyx, and the skin abraded. The birth was ultimately accomplished by the forceps; as soon, indeed, as the short forceps could be effectually applied. Dr. Haslewood considered the causes of the protracted and severe labour to be smallness of the pelvis and ossification of the os coccygis, much incurvated. When pregnancy again took place, I was requested to state my opinion respecting the propriety of inducing premature labour, but before doing so, and recommending the operation, I thought it advisable to consult Dr. Merriman, whose experience on this subject was communicated to me in the following letter.

806.—XXXII.

My dear Dr. Lee,—The case you mention to me is doubtless rare, for you have never seen exactly such a one, nor have I. I recollect one patient in whom the point of the coccyx snapped in three subsequent labours and healed without difficulty; and I have known one or two others where the parts snapped in the first labours and no ill consequences followed.

One of my patients, whose case resembles most that which you refer to, had so great a *turning up*, I believe I must call it, of the coccyx, as to delay the labour for probably two hours, and I was strongly tempted to use the forceps, but they were not applied, and both mother and child did well. I attended her three or four times afterwards, and there was always some delay on account of this straitness, but not so great as at first. There was a considerable bulk of anchylosis; the mischief was produced by a fall down stairs when about 12 or 14 years old.

I agree with you in thinking that it would be right, under all the circumstances of the case, to induce labour at eight months, rather than to leave the poor woman to the chance of again losing her infant, but of course your friend will institute a careful inquiry first, as to the present condition of the parts.

Believe me, dear sir,

Very truly yours,
SAMUEL MERRIMAN.

34, Brook Street, Oct. 9, 1841.

"I find on examination," observes Dr. Haslewood, in his letter in reply, "that the last bone of the os coccygis is not ossified, but that there is the same projection as before, depending, I now think, more on malformation of the sacrum than merely on the os coccygis. I am no draughtsman, but the line above is an attempt to convey my impression of the curve; in fact, the sacrum curves forwards, so as to form an obvious obstruction, and at the end thereof the last bone of the os coccygis is moveable. My impression was that the latter bone was not

Q

moveable, but in this I believe I was mistaken, as the obstacle seems very much the same as before." Premature labour was induced, and the child was born alive without artificial assistance, but has not been reared. Pregnancy again took place, and the propriety of inducing premature labour came again to be considered. The accuracy of Dr. Haslewood's description was fully verified by the most careful examination which I could make of the pelvis, but I was induced, from the extraordinary state of mental anxiety and dread of the operation entertained by the lady, to recommend her to be allowed to go to the full period, and the delivery to be completed with the forceps as soon as it should become evident that the head could not pass without suffering from the pressure of the point of the sacrum and coccyx. The child was born by the natural efforts, and is now alive.

Tumors within the pelvis occasioning difficult parturition are not of very frequent occurrence, but when large, hard, and immoveable, they produce nearly the same consequences as distortion and exostosis of the pelvis, and require, in many respects, a similar mode of treatment. The greater number of these tumors are enlarged ovaria, which have become fixed by adhesions to the uterus and rectum. Some are fibrous tumors developed in the walls of the uterus, and others grow from the ligaments and bones of the pelvis, and are situated in the loose cellular and adipose substance lying between the bones, and the bladder, the vagina, and rectum. These latter form by far the most rare variety of pelvic tumors which obstruct the progress of the child's head during labour, and their diagnosis is extremely difficult and obscure. I shall relate the following examples of these tumors growing from the pelvic ligaments and bones, for the purpose of impressing upon you the necessity of observing the greatest caution in adopting the bold and successful plan of treatment pursued by Dr. Drew and Dr. Burns.

Difficult labour from fibrous tumors attached to the sacro-sciatic ligaments and bones of the pelvis.

In February 1803, Dr. Drew examined the body of Mrs. Shaw, æt. 37, the mother of six children, who had died from a tumor within the pelvis, which compressed the bladder and rectum. It was situated in the loose cellular and adipose substance between the viscera and bones of the pelvis, and it grew by a strong root, of a hard gristly nature, from the left sacro-sciatic ligament. Having cut through the root the tumor came away, like an almond blanched from its skin, so slightly was it attached to the parts that surrounded it. "The tumor was per-

fectly round, about 16 inches in circumference, of a fat gristly substance, without any appearance of circulation in it. No artery entering it. No vein proceeding from it. Unconnected with the arteries which run down from the internal iliacs to supply the contents of the pelvis. It seemed the production of the ligament alone. Could not an incision have been made at one side of the perineum and anus," inquires Dr. Drew, "backwards, towards the os coccygis, and the root of the tumor, proceeding from the sacro-sciatic ligament, be come at, and cut through? And as it was so easy to detach it from the contents of the pelvis, might not it have been without much difficulty removed? Should any artery in the neighbourhood of the perineum be cut, it could easily be taken up; and as the tumor itself received no branch from the internal arteries of the pelvis, the hæmorrhage, in all probability, would not be great."

Six months after this dissection the following case occurred, which is extraordinary alike for the accuracy of the diagnosis and the facility and success of the formidable operation performed. A tumor, much larger than the fist, was removed through the outlet of the pelvis, and in three days the patient "was able to suckle her child, and the wound perfectly healed."

Aug. 26, 1803, I was called on, says Dr. Drew, to Mrs. M——, of Lismore. She had been two days in labour before I saw her, and was attended by Dr. Power, Dr. Hannan, and Mr. Pack, Surgeon to the 41st Regiment of Foot. Those gentlemen were puzzled at the presentation, and so I should have been, had I not met with the preceding case. It was exactly the same. The tumor grew out of the right side, and occupied the whole cavity of the pelvis so completely as to admit of passing only one finger between it and the pubis, by which I could scarcely reach the head of the child. She said she had for some months laboured under dysuria, so that the catheter had been employed by a surgeon who attended her, and who attributed that affection to her state of pregnancy, supposing it to arise from the pressure of the gravid womb: that she had lately acquired the knack of pressing on the tumor with her finger, which enabled her to make urine without assistance. Being convinced of the nature of the case, I related that of Mrs. Shaw, and represented the possibility of removing the tumor with a prospect of success, at least with more than would attend the Cæsarean section. Embryulcia was out of the question; it could not be performed: there was no room to extract the child: and if it had been practicable, since the mother's life could be prolonged for a short time only, it involved in it a crime; and to leave our

patient undelivered was cruel and unprofessional. They therefore willingly consented to the operation proposed. Having laid my patient on a table in the posture of operating for lithotomy, my assisting friends holding each a knee, and the midwife the shoulders, I made my incision by the right side of the perineum and anus, towards the os coccygis, and with the second stroke of the scalpel brought the tumor into view. I passed my finger before and behind its root, which I easily divided with the knife, and introduced my hand, and detached it from the side of the pelvis; withdrew that hand, and introduced the other, by which I separated it with equal facility from the vagina and rectum, and, to their great pleasure and surprise, brought it away. A gush of blood now took place, and I crammed in a sponge, which instantly checked it. An artery near the perineum spouted. This I laid my finger on, and could, if necessary, in any instant have taken it up; but all hæmorrhage completely ceased. We now turned our attention towards the support of our patient: assured her all danger was over. No fainting occurred; her pulse was sufficiently distinct and strong. We administered a little wine, but the best of cordials was the great pleasure and satisfaction she saw in the countenances of us all. A labour pain now came on, succeeded by another and another; the head descended into the cavity of the pelvis; the sponge was protruded from the wound. We retained her for an hour on the table, expecting she would soon be delivered, but finding her labour grow tedious we removed her into bed. Here we trusted to the efforts of nature for six hours. Finding the child was presenting with its face towards the os pubis, and apprehensive of her wanting strength, I applied the forceps, and delivered her of a living child, which has since continued well. The placenta came down into the vagina, and was easily removed. No hæmorrhage took place. Four stitches were passed through the lips of the wound, and a large sponge was thrust into the valves to keep the sides of the cavity which contained the tumor in contact, and all the other requisite arrangements and comforts were employed. We waited on her in the evening; found her as we could wish; drew off about half a pound of urine with the catheter, for the sponge prevented her from making it herself; left her to repose, and next morning visited her again; she slept well, and complained of little pain from the wound. We drew off her urine, and removed the sponge from the vagina, which I washed out with a syringe, and found it completely free from any injury or ulceration; replaced the sponge, and dressed the wound with a pledget and T bandage.

August 28.—An enema was administered

yesterday morning without effect. Some castor oil was given in the evening, which produced rather too many evacuations; but no bad symptom took place. We removed the sponge from the vagina, and found the space which the tumor had occupied completely obliterated. But two of the stitches gave way, and left the lips in part separated. The sponge was omitted, and the lips brought together again with a strip of adhesive plaster. An anodyne was prescribed, to check the catharsis, and two scruples of bark to be taken three times in the day. Here our report ended, as no unfavourable symptom occurred: I visited her for the last time on the 29th, and found her able to suckle her child; both completely well; the wound perfectly healed, without a vestige of any ill consequence from the operation.

Mrs. M. is a slender and delicate woman, aged about 20, and married twelve months; had once before marriage some suppression of urine, but attended with no pain. The tumor measures 14 inches in circumference, weighs about 2 pounds 8 ounces, and is of the same nature and consistence with that found in Mrs. Shaw. As the above cases are very uncommon—as the operation was attended with unexpected and signal success, and the cure complete—and since many of the profession are inclined to discredit such cases, it may not be amiss to subjoin the testimony of those who were present. I have therefore obtained the signatures of Dr. Power, Dr. Hannan, and Mr. Pack.

In the histories of these very remarkable cases of tumors growing from the sacro-sciatic ligaments, and situated in the cellular and adipose substance between the viscera and the pelvis, there are no symptoms described by which they could be distinguished from ovarian and uterine tumors, the removal of which in this manner no scientific surgeon would recommend. They are related in far too indefinite a manner to warrant us in drawing any conclusion from them, or proceeding to perform this operation where the diagnosis was not more clearly determined. The second case was most successful, marvellously so it is true, the patient being well in three days; but this is no test of the propriety of the operation, or proof that the case is a safe guide to us in practice. I cannot recommend you under similar circumstances to go and do likewise, as some have advised, but it is proper that your attention should be directed to the possibility of such a case occurring, and the necessity of examining in all possible ways, if such a case should present itself, so as to establish a diagnosis by which you might be prevented from being misled. I have never seen a tumor growing from the ligaments or bones of the pelvis. I have seen many ovarian and uterine tumors filling up the

pelvis, but there is no symptom that I am aware of by which you can distinguish these from tumors situated between the pelvic bones and viscera.

The only case that I know of similar to the cases of Dr. Drew is the following, in which the tumor was exterior to the uterine organs, though adhering to them.

"In a dreadful case which I met with some years ago," says Dr. Burns, "the attachments were extensive, and the tumor so large as to fill the pelvis, and permit only one finger to be passed between it at the right side of the basin. It adhered from the symphysis pubis round to the sacrum, being attached to the urethra, obturator muscle, and rectum; intimately adhering to the brim of the pelvis, and even overlapping it a little towards the acetabulum. It was hard, somewhat irregular, and scarcely moveable. The patient, Mrs. Broadfoot, was in the ninth month of pregnancy. There was no choice except between the Cæsarean operation and the extirpation of the tumor. The latter was agreed on; and, with the assistance of Messrs. Cowper and Russel, I performed it on the 16th of March, a few hours after slight labour pains had come on. An incision was made on the left side of the orifice of the vagina, perineum, and anus, through the skin, cellular substance, and transversalis perinei. The levator ani being freely exposed, the tumor was then touched easily with the finger. A catheter was introduced into the urethra, and the tumor separated from its attachments to that part. It was next separated from the uterus, vagina, and rectum, partly by the scalpel, partly by the finger. I could then grasp it as a child's head, but it was quite fixed to the pelvis. An incision was made into it with a knife as near the pelvis as possible; but from the difficulty of acting safely with that instrument, the scissors, guided with the finger, were employed when I came near the back part; and instead of going quite through, I stopped when near the posterior surface, lest I should wound the rectum, or a large vessel, and completed the operation with a spatula. The tumor was then removed, and its base or attachment to the bones dissected off as closely as possible. Little blood was lost. The pains immediately became strong, and before she was laid down in bed they were pressing. In four hours she was delivered of a still-born child above the average size. Peritoneal inflammation, with considerable constitutional irritation, succeeded; but by the prompt and active use of the lancet, and purgatives, the danger was soon over, and the recovery went on well. In the month of May the wound was healed. On examining per vaginam the vagina was felt adhering as it ought to do to the pelvis, rectum, &c. The side of the pelvis was smooth, and a person ignorant of the

previous history of the case, or who did not see the external cicatrix, could not have discovered that any operation had been performed. After a lapse of more than fifteen years, she still continues well, but has never been again pregnant."

Difficult labour from ovarian and uterine tumors.

Baudelocque relates a case of ovarian tumor in the pelvis, obstructing delivery, in which Lauverjat had proposed to perform the Cæsarean operation. Baudelocque turned the child, after forcing up the tumor above the brim of the pelvis, but he was obliged to extract the head with the forceps, after the body and extremities of the child had been delivered. The child was dead, and the woman died two days after. The tumor was ascertained on dissection to be an ovarian cyst filled with long hair and nine well-formed teeth. The patient had been in labour 60 hours. If there was space to admit the hand to be passed into the uterus to turn the child, there must have been sufficient space for the employment of the perforator and crotchet. Doeveren had recourse to turning in a similar case, and the mother and child both perished. Dr. Mackenzie turned the child with great difficulty in a case of large ovarian cyst, filling up the hollow of the sacrum, and pressing the os uteri forward to the pubes. The head of the child could not be extracted without long-continued and violent efforts, and the woman died the following day. Dr. Ford relates two cases of difficult labour from pelvic tumors. In the first, as the tumor was large and firm, and did not yield or diminish by the force of the pains, the head was perforated, but the patient died three weeks after. When the body was opened, the tumor was found to be an encysted dropsy of the ovary, in which there was a considerable quantity of hair. In the latter case, which in all its circumstances resembled the former, a trocar was passed through the posterior part of the vagina directly into the tumor. A large quantity of water was immediately discharged, the tumor subsided, and a living child was born without any farther assistance. This patient recovered from the lying-in, but some time after becoming hectic, she died at the end of about six months, though from the symptoms it did not appear that the fever was occasioned either by the disease or the operation. This patient was not examined after death. "Having related these two cases," observes Dr. Denman (1795), "I have said all which I had to advance on the subject, except that I have met with more than one instance of a circumscribed tumor on one side of the pelvis which I at first suspected to be a diseased ovary. But as these tumors have always

given way to the pressure of the head of the child, the passage of which they have only retarded for a short time, I have concluded they were formed either by some soft fatty substance collecting there, or were cysts containing lymph casually effused, and forming to itself a cyst from the cellular membrane. But on making an examination after delivery, the tumors were found to have again acquired their primitive form and size."

Few if any additional facts of importance respecting tumors within the pelvis occasioning difficult parturition, were published from 1795 to 1811, when Mr. Park's paper on the subject appeared in the 2d Vol. of the Medico-Chirurgical Transactions, in which he has related clearly and precisely the following histories.

In his first case the patient had been long in labour, but the head could not enter the pelvis owing to a firm globular tumor situated between the vagina and rectum, which left very little space between this and the pubes. The head of the child was opened and extracted with much difficulty. After delivery, the tumor totally disappeared; the patient had more children afterwards, without any recurrence of the tumor. Mr. Park thought that an attempt should have been made to diminish the bulk of the tumor before having recourse to the crotchet. In his second case he found the pelvis nearly filled by a tumor similar in situation and texture to that in the former case. It was with some difficulty that the finger could be passed between the tumor and the pubis, so as to reach the os internum, till it became a good deal dilated. After a severe and protracted struggle, the delivery was accomplished by the natural efforts, and the child was born alive. After this she had four miscarriages and premature births in succession, each time of twins, from the 4th to the end of the 7th month. The seven months' children were the last of the four; and these were likewise born without any forcible measures. During these pregnancies the tumor by its pressure on the urethra frequently occasioned retention of urine so as to require the use of the catheter, although by the touch little change could be discovered in its bulk. In her next pregnancy she went to her full time of a single child, and after she had been long in labour, the head pressed constantly on the upper part of the tumor, without being able to descend into the pelvis. The lancette cachée was conducted along the finger to a part of the tumor which felt thinner than the rest, and three or four scratches were made till the parietes felt thin, and the instrument was then forced into a large cavity which was filled with a bloody sanious fluid with a number of flakes of membranous substances resembling the

strippings of tripe; some of these were as large as a quarter of a sheet of common paper. The tumor was completely evacuated by the next pain, and in two or three more the child was expelled. The recovery was slow after this delivery; a very considerable offensive discharge ensued from the incision, with pains in the loins, debility, and symptomatic fever. In two months the symptoms disappeared, but the healing of the tumor and consolidation of its cavity occasioned a considerable stricture, so that the next labours were also difficult.

In the next case related by Mr. Park there was a considerable tumor, like those already described, filling up a considerable part of the pelvis, but of a less firm texture, and not so globular, being of a more irregular oblong figure. The woman had been in labour two days; her strength was not much exhausted, and the head pressed more into the pelvis than in either of the former cases. It was determined to leave the case to nature for a time, and perforate the head if requisite. The child was expelled by the natural efforts on the following day, but she died three days afterwards with vomiting and constipation. The nature of the tumor was not ascertained. In the 4th case a tumor filled the pelvis, and kept the head of the child above the brim after the labour had continued long and exhaustion had taken place. An incision was made into the tumor, but no cavity discovered. Nothing but blood was discharged. The head of the child was opened, and the patient recovered without much difficulty. In the last case an ovarian cyst filled the pelvis so completely that the os uteri could not be reached. In the evening, after slight pains had continued all day, it was reached with some difficulty above the symphysis pubis, and the head was felt presenting. The night passed over with little alteration, and the whole of the next day without much more. Strong pains then came on, and continued the whole of the following night, which dilated the os uteri to the diameter of three inches. An opening was made into the tumor after the labour had continued some time longer, and a bloody serum drained off, so as to render the tumor quite flaccid, and to diminish its bulk at least two-thirds. As the head descended into the pelvis, it became totally evacuated. Immediately after the puncture was made, the head began to dip into the pelvis, and to dilate the os internum more fully; but the child proving a large one, it required eight hours more of strong labour to complete the delivery, although the tumor could not oppose any further resistance. The long pressure on the head destroyed the child, but the patient recovered.

Mr. Park has given no opinion respecting the origin and nature of these tumors, most

of which were probably ovarian. The practice adopted by him was certainly extremely judicious; but it did not differ from that which Dr. Ford had recourse to in his cases. In the pathology and treatment of these tumors, therefore, there is nothing absolutely new in Mr. Park's paper; but its publication was of use by directing the attention of practitioners to the subject.

In the third volume of the *Medico-Chirurgical Transactions*, Dr. Merriman (1812), has related a case of difficult parturition occasioned by an ovarian cyst in the pelvis, which occurred in 1804. After thirty-six hours had passed in severe and ineffectual pain, the head was perforated, and extracted with much difficulty. Soon after this child was born it was ascertained that there was another in the uterus, which, being smaller, was expelled by the natural efforts, and appeared to have been dead some hours. The patient died in a few days from peritoneal inflammation, and the right ovary, about the size of a trap-ball, and in a state of high inflammation, was found lying between the rectum and the vagina. The brim of the pelvis was narrow. Dr. Merriman also relates a case which had occurred a short time before in one of the London lying-in hospitals, in which the labour was protracted by an ovarian tumor in the pelvis, consisting, like Baudelocque's, of fatty matter, intermixed with hair and teeth. The head of the child was perforated, and the woman was delivered, but did not long survive. "Upon the whole, therefore," he says, after alluding to all these cases, "I am disposed to believe that, where the tumor in the vagina occupies a large space, it would be a more warrantable practice to remove it by excision, if it consisted of solid substance, and certainly to puncture it if it contained a fluid, rather than to expose the child to certain death, and the mother to great hazard, by the use of the perforator." Dr. Drew's cases are quoted to sanction, in some degree, the attempt to remove solid ovarian tumors by excision during labour; although, as has been already stated, it was not an ovarian tumor which Dr. Drew removed through the outlet of the pelvis.

Other five cases, of a nature similar to the preceding, have been recorded by Dr. Merriman in the tenth volume of the same work. In the first the delivery was accomplished with the greatest difficulty after the head of the child had been opened. The tumor, which was large and elastic, occupied the back part and left side of the pelvis, which was distorted; and it was not opened, Dr. Denman and Mr. Croft not being satisfied that it contained a fluid. The patient ultimately recovered, after remaining long in extreme danger. The labour lasted ninety hours. In the second case there was a tense,

elastic, lobulated tumor, between the vagina and rectum, which was punctured with a trocar from the rectum; but the matter it contained was of the consistence of honey, and would not flow through the trocar. The patient was left twenty-four hours in labour. After this, when the tumor was somewhat diminished in volume, but the head of the child was not at all advanced, the head was perforated, and eight hours after it was extracted. The tumor had ceased to be felt before this. Eighteen months after she died hectic. The effects of chronic inflammation were apparent in the abdomen; and the ovary, which was in its natural situation, equalled a small lemon in size, and contained sebaceous matter, and a tooth lying loose among it. The tumor in the third case was neither so large nor incompressible as in the other instances. As the head of the child was forced down at each pain, the tumor yielded or became flattened against the back of the pelvis. The hand was passed into the vagina, and the tumor pushed up above the brim; and thus room was procured for the head to pass, which in less than an hour was protruded through the os externum. The child was alive and healthy. The right shoulder presented in the fourth case, the history of which was communicated by Mr. Hardwick, of Epsom, and the tumor was not connected with the ovaria. It was situated between the cervix uteri and the rectum, forming a cushion in the hollow of the sacrum, the superior portion rising an inch or more above the projecting part of that bone. Its shape was elliptical, flattened at the anterior and posterior surfaces by the pressure it had sustained; its size was that of a large orange, or the head of a foetus at six months. It was contained in a cyst, apparently formed of the peritoneal reflection at its superior part, and of the cellular membrane connecting the rectum and vagina. The ovaria were of their proper size and in their natural situation. The anterior part of the rectum was inseparably connected to the tumor. The whole mass was soft and compressible; and although the cyst was in most parts very thin, it had not given way by the force employed in the delivery. The contents of the tumor were regularly disposed in layers, the concave surface of one portion being exactly adapted to the convex surface of the next, and the diameter of each about the size of a sixpence. Their colour resembled tallow, and they appeared to consist of adipocercous matter. The woman was left long in labour before the operation of turning was performed. The crotchet and blunt hook were employed before the head could be extracted. Alarming symptoms took place immediately after delivery, and she died in less than half an hour, before the placenta could be extracted. She

was 44 years of age, and had been delivered of six children. In her first and sixth labours the forceps were used; but no tumor existed at the time of her former labour, at least none that could be detected. The fifth case also terminated fatally. After labour had continued a great many hours, a small-sized curved trocar was passed up the rectum and pushed into the tumor, and about six ounces of a pale yellow fluid escaped. The size of the tumor was diminished so much that it was expected the child would pass by the natural efforts; but on the following day it was found necessary to deliver by opening the head. She died in a few days, with the usual symptoms of uterine inflammation. The right ovarium was found imbedded between the vagina and the rectum: it was about the size of a sheep's bladder, and contained fatty matter, a large quantity of hair, and the rudiments of two or three teeth.

That labour was allowed to go on too long in most of these cases there can be little doubt. In cases where the tumor is large, Dr. Merriman infers, from the results, that the perforator alone cannot be trusted to, and that experience does not warrant the practice of turning and delivering by the feet. "Upon the whole," he thinks, "the evidence we at present possess is most in favour of opening the tumors; for of the nine women who recovered more or less perfectly, five appear to owe their safety to this operation; and of the three children born alive, or supposed to be so, two were preserved by the same means."

Nothing is said by Mr. Park or Dr. Merriman, in the fourth edition of his work on Difficult Parturition (1826), respecting the propriety of inducing premature labour where it is known during pregnancy that a tumor occupies the cavity of the pelvis, and is fixed within it. As early as 1815 it appears, however, from the history of the following case, No. 60, that this subject had been fully considered by Dr. Ramsbotham, Senior; and that the operation was sanctioned by other two professional accoucheurs, and would have been performed if it had been possible to reach the os uteri.

"In April 1815, I was bespoke to attend a lady near the Mansion House; and upon calling upon her, I learnt that some years ago she had passed a living child without difficulty; that about two years before she had a bad labour, in which, after its continuing for several days, the child was destroyed, and obliged to be extracted by force, and that she narrowly escaped with her life. Having now advanced beyond the fifth month of pregnancy, she suffered much uneasiness in her mind for the result of her ensuing accouchement, and wished to place herself under my care. She was tall in person and apparently well formed; but it

was evident that some malformation or disease had taken place in the pelvis between the two preceding lyings-in: I was therefore anxious to ascertain whether the same obstacle to the passage of the child still existed. An examination being allowed, I found a large tumor of considerable solidity, but of what description I am still ignorant, filling up nearly the whole cavity of the pelvis, so as scarcely to admit the free passage of two fingers to the brim. This information placed me upon the alert, and gave me some idea of the difficulties I should in future have to contend with. I extended my inquiries to the nature of the preceding labour, the degree of difficulty attending it, and the danger following it; and having made myself acquainted with these facts as far as I was able, *I proposed the induction of premature labour, as the most likely means of diminishing the patient's sufferings.* The proposition was readily acceded to. I was now desirous of a consultation, as well for a sanction to the proceeding as for determining the most proper time to put it in practice. Two celebrated professional accoucheurs met me in consultation with Mr. —, who had been present at the preceding difficult labour. After all the inquiries we severally could make, the induction of premature labour appeared to all to be impossible, inasmuch as the tumor so far prevented the introduction of the hand that the finger could not be carried sufficiently high to reach the os uteri. In this dilemma we had no alternative but to let the woman go her full time and take her chance. Her labour commenced on the fore part of Tuesday, June 25th, and went on slowly till evening, when the pains began to quicken. About midnight I was called, and found the os uteri dilated, the liquor amnii discharged, the pains very active, the head at the brim of the pelvis, and scarcely sufficient room to admit two fingers through the pelvis. I sent to Mr. —, who had been requested to be again present, but he was not at home. The pains rapidly increasing in power, I determined immediately upon perforating the head, with the then intention, after evacuating the brain, of leaving it a few hours for collapse before I extracted it; but this intention I did not pursue. After the perforation was made, the labour pains soon became expulsive: I was now desirous of taking advantage of their powerful efforts to assist me in the extraction of the head; I therefore introduced the crotchet, and getting a good purchase, the vagina at the same time somewhat relaxing, I got down the head by little and little, till I at length extracted it quite crushed together. The operation took up more than four hours of very great exertion on my part. The body of the child soon followed, and the placenta was naturally

excluded. The tumor was still in its original situation, but the vagina felt flaccid and loose. I was apprehensive that subsequent mischief might ensue from the pressure of the head, and the degree of violent force I was obliged to exert in the extraction of the head; but none to my knowledge followed. Febrile symptoms, which took place, gradually declined, and she completely recovered.

Dr. Ramsbotham has related the history of another case, No. 61, which occurred in 1818, in which he proposed to induce premature labour in the eighth month of pregnancy, but the patient would not consent to the operation. The first volume of Guy's Hospital Reports, published in 1836, contains a paper by Dr. Ashwell, entitled, *Observations on the Propriety of inducing Premature Labour in Pregnancy complicated with Tumor*, in which he strongly recommends, to obviate the morbid changes in fibrous tumors resulting from pregnancy, the same operation as proposed by Dr. Ramsbotham; but in none of the six cases related in the communication was premature labour induced. In the second volume of the same work there is a case recorded by Dr. Ashwell, of cancer of the external parts with pregnancy, in which the membranes were punctured; but the woman died soon after delivery. The seventh volume of the same work contains *Observations*, by Dr. Lever, on Pelvic Tumors obstructing Parturition, with cases; but in none of the cases, I believe, was the operation actually performed; so that our experience upon this point is still extremely limited.

The following cases of pregnancy and difficult labour, from ovarian and uterine tumors, have come under my observation; and it will be seen that, in one of them, the induction of premature labour did not prevent fatal inflammation and suppuration of the tumor.

In the summer of 1839, I saw a patient some miles from London, whose labour was protracted by a tumor within the pelvis, probably ovarian. She had been delivered before repeatedly, and all her labours had been natural. After she became pregnant on this occasion, she thought, from feeling two distinct swellings in the abdomen, that she had twins. When I first saw her, she had been in labour nearly twenty-four hours. The head had scarcely begun to enter the brim of the pelvis, the cavity of which was occupied by a tumor the size of a cricket-ball, or larger. Whenever a pain came on, the tumor was pressed down before the head. The forceps had been applied, but the head could not be brought before the tumor, though great and long continued efforts had been made to drag it forward. I opened the head, and had much difficulty

afterwards in drawing it down with the crotchet. In 1841, the same person being in the seventh month of pregnancy, Mr. Pickering, of Hammersmith, requested me to make an internal examination, to determine the propriety of inducing premature labour. As the tumor had risen out of the pelvis, had not enlarged, and the brim was occupied with the lower part of the uterus, I thought it best not to interfere. She went to the full period, and was safely delivered of a living child.—In another case of very protracted labour, where the hollow of the sacrum was filled up with a large ovarian cyst, I delivered by craniotomy, and the patient recovered favourably.—A woman, æt. 30, in the fifth month of her first pregnancy, began to suffer from sickness, fever, and constant pain and distention of the abdomen. On examination, it was easily perceived that the gravid uterus was pressed to the left side by a hard, painful, lobulated tumor on the right. This continued rapidly to enlarge, and to become more exquisitely painful, though leeches were applied in great numbers over the tumor, and calomel, antimony, opium, and cathartics, were administered internally. The painful distension of the abdomen soon became so great that it was necessary to obtain relief by inducing premature labour. This was easily done. For a short time after delivery the symptoms were less severe, but the fever, sickness, and painful distension, soon returned, and proved fatal. A fibrous tumor, in a state of inflammation and suppuration, was found attached by a large root to the right side of the body of the uterus. The peritoneum which covered it adhered to the parietes of the abdomen, omentum, intestines, and liver. Numerous small fibrous tumors, the blood-vessels of which have been injected, were found imbedded in other parts of the parietes of the uterus. These were in a healthy state. I was called to this case by Mr. Walker, of Marylebone Street, and it occurred in the summer of 1840.—On the 6th December, 1840, Dr. Brown requested me to see a case of pregnancy complicated with an ovarian tumor. This tumor had appeared five years before conception took place, and had slowly enlarged. The patient was in the sixth month of her first gestation, and the abdomen was enormously distended, and a fluctuation was perceived on percussion. The difficulty of breathing was so urgent that it was impossible for her to remain an instant in the horizontal position. We considered it necessary to induce premature labour, but the os uteri was so high up, and directed so much backwards, that great difficulty was experienced in passing the stiletted catheter into the uterus, to perforate the membranes. The anterior lip of the os uteri could only be

reached with the tip of the finger. An instrument with a sharp point and a smaller curve than that employed could not have been introduced in this case to evacuate the liquor amnii. On the 7th, labour pains commenced. Venesection and opiates were employed to promote the dilatation of the os uteri. The nates presented, and on the 9th a dead foetus was expelled. The relief from the delivery was great, though the abdomen continued large, and the fluctuation distinct for several weeks. August 10th, 1841. The ovarian tumor has been considerably reduced in size since the repeated application of leeches and the long-continued use of the liquor potassæ. The general health is nearly in the same condition as before pregnancy. She has again been pregnant, gone to the full period, and been delivered without any artificial assistance. Inflammation of the tumor followed, but recovery has taken place.—Twelve years ago, with Dr. Merri-man and Dr. John Prout, I examined the body of a woman, æt. thirty, who had died from malignant disease of the right ovary a few days after delivery. In the 4th month she began to suffer from uneasiness in the hypogastrium, and irritability of stomach. The countenance became sallow, and the constitutional powers greatly reduced. The abdomen not long after began rapidly to enlarge, and before the end of the seventh month it had attained the size it usually acquires at the full period. An enormous cyst, which contained a dark-coloured gelatinous fluid, was found on dissection adhering to the right ovary, and within this cyst were a number of others of different sizes and shades of colour, which, when cut open, presented the true encephaloid or hæmatoid fungous character.

I have very little to say respecting protracted labour from *cicatrices of the vagina* and *cancer of the os uteri*. Where it arises from the first of these causes, the pressure of the head of the child is generally sufficient to overcome the resistance, if the uterine contractions are strong. It is proper in all cases to wait, and see what the natural efforts can do, before interfering. In one case where, from the great extent and hardness of the cicatrix, it seemed impossible for the dilatation to be effected without assistance, the most striking effect was produced by a copious venesection. In another case the edge of the cicatrix was slightly cut with a scalpel. In a third, where complete exhaustion had taken place, I extracted the child alive with the forceps; but the cicatrix was extensively lacerated. To prevent women who have cancer of the os uteri from dying undelivered, if allowed to go to the full period of pregnancy, it would be justifiable to induce premature labour even before the end of the seventh month.

CLINICAL LECTURES, *Delivered at St. Thomas's Hospital,*

BY SAMUEL SOLLY, Esq. F.R.S.

Assistant-Surgeon, and Lecturer on Clinical Surgery, at St. Thomas's School.

ON INJURIES OF THE HEAD.

GENTLEMEN,—One of the accidents admitted last week, permits me to direct your attention to the subject of injuries of the head. These injuries are as important in a practical as they are interesting in a physiological point of view.

For beautifully as nature has protected the brain, the case which has been contrived for this purpose cannot be interfered with, without our fearing some disturbance of the organ it contains. And we find in practice that all injuries to the skull and the membranes which cover it without or line it within, are liable to be attended with disturbance of the instrument which the mind employs in its communications with the external world. The limits of a clinical lecture necessarily forbid my entering much into either the anatomy or physiology of the subject; nevertheless I think it desirable briefly to remind you of the varied structures which are implicated in these injuries. And as in the treatment of them it is the brain which we have especially to consider, let us review them each from the surface of this organ to the external world.

This surface of the brain, from its ganglionic nature, is so vascular, that a special membrane, the pia mater, supports its vessels, and forms its first covering. Next in order is the arachnoid, a serous membrane, placed here to prevent that friction which the constant motion of the brain renders the presence of necessary.

To the physiologist the existence of this membrane affords ample proof, even if other proof were wanting, that the brain during life moves within the skull; and to the surgeon it is interesting, as it impresses him with the importance of preventing any alteration in its structure, however slight, which could interfere with this intention, or cause the friction which its healthy condition prevents.

The next is a strong fibrous elastic membrane, which lines the bony case in which the brain is placed. It is split into bands, which are stretched in different directions like the springs of a carriage, to prevent jolts and jars. The bony covering itself is not homogeneous, but constructed internally of a dense unyielding plate, which like the steel of a helmet is to protect the brain from sharp-pointed instruments; while the outer, though less dense in material, is equally well constructed for its guardian office. The

very coverings of the skull itself are important in their physiology to the surgeon. The external periosteum which nourishes the bone, and with its thousand vessels inosculates at all points with those of the dura mater within; the loose and delicate cellular membrane which connects the periosteum to the firm tendon of the occipito-frontalis; and though last in our number, not the least in practical importance, the skin, which in this situation is perhaps more interesting to the surgeon in connection with its injuries and its functions, than the skin in any part of the body.

On the present occasion I shall not call your attention to the subject of scalp wounds; but I shall take the first opportunity which is afforded me by the reception of a well-marked accident illustrating this important branch of surgery. To-day we must confine our attention to fractures of the skull, their consequences, and the treatment to be employed.

The subject of the present case, John Wingrove, æt. 33, a stone Sawyer, of healthy appearance, was admitted into St. Thomas's Hospital, at $\frac{1}{4}$ before 8 A.M. on April 13th, 1843, with a compound fracture of the skull. The wound was about two inches and a half in length on the right side of the head, near the posterior extremity of the vertex. The scalp was completely divided, and the bone perfectly bare. The parietal bone was fractured in a fissured form; a portion of the outer table being depressed so that the fractured edge of the skull was distinct above it. Whether the inner table was also fractured it was impossible to say positively, but my belief is that such was not the case. [A sketch was handed round the theatre, shewing the situation and extent of the injury.] Some blood flowed from the bone, but not much. A portion of the leather lining of his cap had been driven into the wound, and was nipped so closely by edges of the bone that it was not easily removed. A small artery was bleeding on the divided edge of the scalp. I saw this man at a $\frac{1}{4}$ before nine, about one hour and a quarter after it had happened. He was quite sensible; both pupils acted perfectly naturally to the light; he complained of pain in his head, but referred it principally to the forehead. There was no paralysis of any kind; pulse small, only 60 in the minute. The accident occurred at the New Royal Exchange, and was occasioned by a blow from the head of a mason's hammer which flew off from the handle, and falling about 30 feet struck him on the head and glanced off. He was completely stunned by the blow, and had no recollection of being put into the cab by which he was conveyed to the hospital, but he recovered his senses before he arrived there.

I ordered Cat. Lini. to the wound.
Calomel, grs. v. 3tâ horâ.

$\frac{1}{2}$ past 12 P.M.—No change.

$\frac{1}{2}$ past 10 P.M.—Pulse 80, but not strong; says his head is much better, but he feels very tired and cannot sleep, but this he is not surprised at, as he never can sleep well if he has not had his usual day's work.

He has taken five doses of the calomel, and the bowels have been copiously relieved; as he has no untoward symptoms, I have discontinued the calomel.

Not more than two or three ounces of blood have been lost from the wound.

14th.—Going on well in every respect; no bad symptoms; almost free from pain in his head; pulse 64; suffers a little from cough.

Linc. pro tussi.

15th.—Has had a good deal of pain in the forehead, which he attributes to the shaking of his head from his cough. His pulse 86, but not strong; loud respiration over the whole chest. No pain in the wound or neighbourhood; bowels not open to-day.

Ordered—Calomel, gr. v., 4tâ horâ;
Hirud. xxx. lateri capitis dextro. Head shaved. Pil. Ipecac. c. Conio, gr. v. 6ta. horâ. Emplast. Lytt. pectori.

16th.—Much better; his cough very much relieved; free from pain in his head; bowels not open to-day; mouth tender.

Ordered—M. S. C. stat. To omit the Cal. till to-night. A poultice to the blister.

17th, 9 A.M.—Has had a bad night; head very painful in the frontal region; pulse small, 80; looks uncomfortable; wound healthy, suppurating.

Ordered—Hirud. xxx. stat.

12 P.M.—Better; very little cough.

To omit the Pil. Ipecac. c. Conio, and to rep. Hirud. h. n.

18th.—Much better as regards his head, but the cough still troublesome.

To repeat the Ipec. c. Conio, the blister on the chest not having risen well; to paint the throat and chest with tincture of iodine. Pulv. Rhei c. Cal. grs. xv. h. n.

19th.—Much better in every respect.

20th.—Free from pain in his head, and the cough nearly gone.

21st and 22d.—I did not see him.

23d.—Going on well in every respect.

Let us now direct our attention to the man's symptoms on admission, and the treatment adopted. First, here we had a fractured skull with depression of the bone. Now some 50 or 60 years ago the trephine

would have been immediately applied with the view of elevating the depressed portion. This operation, however, in the present day, is not considered justifiable in the absence of symptoms of compression, or direct irritation of the brain.

In the examination of a case of this kind, then, it is extremely important for you to enter minutely into all those signs which indicate any injury to the brain. First, the mental condition—this was perfectly normal; he was quite sensible, and his manner natural. Next, the state of the pupils—the iris is placed before that expanded surface of the optic nerve, the retina, as an intelligent curtain to guard it from injury. The vital contrivances by which it acts, and by which its action is directed, are so beautifully perfect that the extent of the opening of the curtain is indicative of the state of the nervous apparatus it is destined to protect, by preventing such an amount of light impinging upon it as would be liable to injure it. In disease of the globe of the eye, the dilated pupil indicates more or less pressure on the retina by some cause in the globe itself, such as a permanently turgid choroid, &c. But if with a healthy eye, but in connection with a blow on the head, we find a dilated pupil, then we have the sign of some pressure or injury to the nerve in its course within the skull, or the ganglia in which it terminates.

The dilated pupil, then, indicates very serious injury to the optic nerve, or the nervous centres with which it is connected, though it may happen, as in the case of very severe concussion, the injury is remediable. The contracted pupil, on the contrary, indicates an irritability of the nervous instruments, an undue excitement of their natural function, not an obliteration of it. You will sometimes see, in the case of injury of the brain, dilatation of one pupil and contraction of the other; where this is the case you will find the most severe injury of the brain on the side opposite the dilated pupil. I have several facts to prove this assertion, which I shall relate on a future occasion.

The next point to which our attention was directed in reference to the prognosis of the case, was the state of the wound, and the blood which flowed into it. Now the blood which flowed into the depression might be from a wounded artery of the dura mater, or simply from the bone. If from the dura mater, the injury was of course very serious: this I hoped, and believed, from its extent at the time was not the case, as I stated to one of the pupils who inquired of me what I thought of it. It soon ceased, proving that this supposition was correct; which is satisfactory, as it goes far to shew that the inner table is not fractured. That the outer table may be fractured without the inner is

proved by this preparation, where you see considerable depression of the outer without any whatever of the inner table.

We will next consider our treatment of the case. I ordered him a poultice to his head of linseed meal, to be separated from the wound by a piece of thin rag. This I did in order to encourage the bleeding, at the same time giving directions to Mr. Fixot, the dresser, to carefully watch its effects. I ordered Hydr. chlorid. gr. v. 3tiâ horâ. Now, although this man was at present free from all symptoms of serious injury to the brain, notwithstanding the depression of the bone, a few hours might entirely change his condition. Reaction had scarcely taken place from the shock of the injury, and there was no indication for the abstraction of blood from the arm. The nature of the injury was, however, such as we find frequently followed by inflammation of the membranes and substance of the brain, and to avert this calamity, I ordered the calomel.

In speaking of inflammation of the membranes of the brain let me impress upon your minds that these membranes are seldom inflamed without this hemispherical ganglion either being positively inflamed itself, or directly suffering by irritation from the effects of the contiguous inflammation; and inflammation of the pia mater is in reality inflammation of the ganglion itself, which I do not think the practitioner sufficiently considers. Now as this ganglion is that portion of the brain which more immediately than any other ministers to intellect, inflammation of it causes derangement of the intellect, and of all effects of inflammatory action on the human frame, I need not say, this is most to be dreaded. You cannot, therefore, be too much on your guard to prevent its intrusion, and to distinguish it almost before it is set up; for when once set up, it is not so easy to arrest it, and when arrested it too often leaves behind consequences which are felt for the remainder of life.

The following case, the subject of which was admitted about two years ago, so well illustrates the effect of fracture of the skull in lighting up inflammation of the hemispherical ganglion, and the symptoms of that inflammation, contrasted with the natural condition of that organ after the inflammation had been arrested, that I shall briefly detail it before proceeding further to shew you what might have occurred in this case, if I had not anticipated the threatened evil by precautionary treatment.

Inflammation of the membranes of the brain, caused by fracture of the skull, arrested by antiphlogistic measures, and aconite.

Betsy Rankin, set. 18, works at the Rope-walk, admitted April 20th, 1841, Luke's ward for Dorcas, under Mr. Travers, Mr.

Solly in attendance. Her mother stated that she had been thrown out of a swing at Greenwich fair, a week previous to admission; that she was stunned at the time, and had suffered from severe pain in the head since; but she was not considered to be seriously injured. At the time she presented herself she exhibited an unnaturally excited appearance of the eye; she complained of violent pain in the head, but her answers to questions were perfectly rational.

One of my colleagues happening to see the case immediately after she was in bed, before I came up into the ward, and finding an irregularity of the surface of skull, cut down upon it: the pain of the incision made her very violent, and disgustingly abusive in her language. The incision permitted the escape of some coagulated blood. The division of the temporal artery gave rise to a free hæmorrhage of about 8 ounces. It exposed a fracture extending horizontally through the parietal bone to the frontal bone, and another extending perpendicularly from the above.

11 P.M. same day.—Still very violent and abusive in her language when spoken to; otherwise quiet and dosing; tongue foul; pulse quick. I explained to the sister of the ward that her violent language was to be considered as a symptom of disease, and that every thing must be effected by a soothing system and by kindness. This was scarcely understood at first, but the plan was most fully carried out, and its value afterwards most thoroughly appreciated by the sister.

Ordered—M. S. C. stat. Cal. gr. iij. quaque tertia hora.

21st.—Bowels freely opened; last evacuation about 3 o'clock was watery; her manner is still excited, but she expresses herself much relieved, adding she only wants to be quiet. On account of the diarrhoea I ordered the Cal. to be discontinued, and Hydr. c. Creta gr. iij. 6ta quaque, instead.

22d.—As the bowels are now quiet, ordered the calomel to be renewed; rather more rational.

23d.—Bowels relieved, but not purged; complains of pain in her head, which is unnaturally hot. Ordered 12 leeches to be applied, if the sister of the ward could persuade her to have them on, but not to use any violence.

24th.—The leeches were applied as directed without much difficulty; her head is relieved, and she is quiet, dosing nearly the whole of the day.

I will not detain you by going through the daily reports, but refer to the most interesting.

29th.—Much better; says that she has very little pain in the head, and no heat. Ordered a little fish; her conduct and manner to-day was quiet, natural, and well-

behaved. I found her in the middle of the day sitting up in her bed knitting.

May 1st.—As she was not quite so well to-day, exhibiting some of her previous excited manner, and fearing a return of the inflammation, I ordered, as I did not think her constitution would bear any more calomel,

Aconite gr. j. ter die; Hirud. xij.; Pil. Hydr. gr. v. ter in die.

This last medicine was continued with small doses of blue pill until the 29th, when she was dismissed quite well.

Her manner now was modest and unassuming, and she expressed herself exceedingly grateful for every thing that had been done for her in the hospital.

REMARKS.—This case affords an instance of inflammation of the hemispherical ganglion caused by injury to the skull and membranes of the brain. I regarded the girl's excited manner, her disgusting violent language, and her quickness and cunning, all as true marks of inflammatory action in this portion of the brain. When I first stated to the pupils that I regarded her language as the effect of disease, and not habitual to her, it was remarked that she was not at all insane, she was quick enough, she knew what she was about as well as any girl in the ward, and that she must be a downright bad one. The correctness of my opinion was proved by the altered manner of the girl as soon as the inflammation was entirely subdued by decided but moderate antiphlogistic measures. The beneficial effect of aconite was I consider shewn by the retrogression which occurred during its accidental omission.

In the case now in the house the most practical point for our consideration is the recurrence of the pain in his head, which you will remember he complained of when first admitted, shewing that such pain, though brought back again by the cough, was but the result of the original injury, and not, as it often is, merely sympathetic with a disturbed stomach. You will naturally say how is this likely, the forehead was not the immediate seat of the injury, but the posterior portion of the skull? This is true, but it is also true that the brain as frequently suffers from the effect of the *contre-coup* as from the direct blow; and I have no doubt but that the force with which the anterior lobes of the brain were driven against the frontal bone by the shock of the blow was the cause of the pain in the forehead.

We may have ample proof of the fact that the brain may be actually shaken in the skull by a blow, even though the blow does not break the skull. Sometimes, indeed, the brain is actually lacerated by such concussion, but, this I believe, only occurs in old people, where the brain has partially receded from its case in consequence of

senile atrophy. I am well aware that this view of the subject is directly opposed to several very good authorities, but it is not hastily or recently formed. The following cases illustrate the fact.

Laceration of the brain from a blow, without fracture of the skull.

Elizabeth Swannell, æt. 69, a cook, was admitted under the care of Mr. Green into Elizabeth's ward, St. Thomas's Hospital, on the 24th Feb. 1841, at half-past 4 P.M. having received a large contused wound, which exposed the bone over the right eyebrow; no fracture or further external injury could be detected.

Symptoms on admission.—Perfectly insensible and motionless; left pupil very much contracted and fixed; the swelling of the surrounding parts prevented the state of the right being ascertained; breathing laboured, with a stertorous noise; pulse 96, full, and not easily compressed; extremities moderately warm; fæces and urine involuntarily passed; great rigidity of the muscles, especially of the right arm and left leg; frothy saliva issuing from the mouth. No spirituous odour could be detected in the breath.

History.—Shortly after 2 o'clock, while going down stairs, she suddenly fell, and was picked up exactly in the same state in which she was brought to the hospital; was not subject to fits; nobody saw the accident.

Treatment.—A surgeon had bled her in the left arm previous to admission; soon after admission she was cupped to ʒix. from the nape of the neck, a large blister was applied to the back part of the head, which was shaved, and hot water to her feet. Breathing slightly relieved by cupping; pulse continued full, and 92. At 9 o'clock I saw her with Mr. B. Travers, apparently exactly in the same state, except that her pulse varied in frequency from 76 to 92; it was very full, but did not indicate sufficient strength to bear further loss of blood. Her breathing was not quite so laboured. At 11 o'clock I gave her gr. iij. of calomel.

Feb. 25, 9 A.M.—No improvement in respect of sensation or motion; breathing a little impeded by mucus; much frothy saliva issuing from the mouth. She remained exactly in the same state, her pulse continuing full, and about 90, till within two or three minutes of her death, which took place at 10 minutes past 4 P.M.

Post-mortem examination.—The brain did not seem to fill the skull completely. No morbid appearance on the surface of the brain. Tentorium smeared with blood. *Interior.*—Extensive effusion of blood into the left ventricle; some into the right: this effusion appears to have resulted from laceration of the left corpus striatum and thalamus,

also of those fibres of the great commissure which forms the anterior part of the roof of the left ventricle. The lacerated corpus striatum and thalamus were forced into the right ventricle under the fornix, and when first observed looked almost like a medullary tumor with an ulcerated surface. In this case the brain appears to have been lacerated by the contre-coup, to which it was especially exposed from its diminished size in relation to its containing cavity—the result of senile atrophy.

April 4, 1843.—Dr. Bright makes a statement, in the 2d Vol. of his Reports of Medical Cases, page 663, confirmatory of the view that I have taken of the brain not completely filling the skull in old persons. See also, p. 683.

The next case will impress upon your minds the serious effects which may be produced by contre-coup, and the necessity and advantage of combating them carefully.

Injury to the head.

William Pearson, æt. about 40, a pot-boy at a public-house, was admitted into George's ward under my care, May 16th, 1842, with a small lacerated wound on the left side of the head; he was intoxicated at the time of admission. The accident was caused by his being knocked down or run over by a cart, I could not learn which.

The case was regarded by the dresser as one of intoxication, and I did not see him until the following morning.

17th.—He now complains much of pain in his head; but, with this exception, there were no symptoms indicative of cerebral mischief, and the headache I considered more characteristic of disordered stomach than brain. There was no drowsiness, and his manner was natural; he referred the pain to his forehead, and not to the seat of injury; his pupils acted naturally.

I ordered—Pulv. Jalapæ c. Cal. ʒj. stat. M. S. C. 6ta. hor. post.

In the evening, finding that though his bowels had been relieved, the pain in the head continued, I ordered him Calomel, gr. v. 4ta. hora.

18th.—Symptoms much the same.

Ordered—Opium, gr. j. at night, and repeat the Cal. and Jalap as a purge.

19th.—Has had convulsive movements of the left side of the face of an epileptic character. Tongue drawn to the left side. Constantly spitting a large quantity of frothy saliva. Both pupils are alike, and slightly contracted, but act freely to the light. Pulse 116, weak. He is quite conscious, and answers all questions naturally, though he has not perfect power of speech. I again examined the head, and, for the first time,

perceived that there was some tenderness on pressure on the right of the head, opposite the wound. Ordered—

Hirudines xx. to the right side of the head; to be followed by a blister.

Opii Tinctura, ℥xxx.; Spirit. Ammon. Arom. ʒss.; Mist. Camphor. ʒj. hac nocte.

20th.—Says he found relief from the leeches, and his head is much better, though still very bad. Pulse soft.

22d.—No appearance of twitching, but tongue still drawn to the left side. Has vomited some greenish bile. Pulse soft.

Ordered—Hirudines xxx. to the right side. Port wine ʒvj. in arrow-root.

23d.—Says her head is much better, though not quite free from pain. Has only had one fit of convulsive twitching since the last report. Pulse still weak.

Ordered—Quinine, gr. ij. b. d.

24th.—Much better; free from headache; no twitching since yesterday; appetite returning. Pulse weak, 80.

Quinine and a pint of porter daily, in addition to the wine.

This man perfectly recovered, and left the hospital quite well soon after the last report.

I have no doubt that the convulsive twitchings in this case were occasioned by some injury to the brain produced by the contre-coup, and the case is instructive from its showing how gradually serious symptoms will sometimes arise some days after the receipt of injury. The result of the local depletion and counter-irritation bear out this view of it, and the general tonic plan which was indicated by the previous habits of the man, and his state of constitution, is important to attend to, from the success which followed its adoption.

These two cases will, I trust, impress upon your minds the importance of attending to possible effects of the contre-coup; and our present case shews how necessary it is to arrest as soon as possible, in all cases of injury to the head, bronchial irritation, occasioning cough. As a general rule, in all recent cases of injury to the brain you would avoid the irritation of a blister, but in the present case it was very evident that the irritation of the cough, and its influence on the brain, was more serious than the irritation of the blister was likely to be. Finally, let me warn you of considering the patient out of danger who has received so serious an injury as in the case before us, notwithstanding its present favourable progress. Its termination, whether favourable or otherwise, I shall call your attention to at our next meeting.

SOME PRACTICAL REMARKS

ON THE EMPLOYMENT OF ARSENIC IN THE TREATMENT OF THE DISEASES OF THE SKIN.

BY JOHN E. ERICHSEN.

[Continued from p. 202.]

THE circumstances that contraindicate the employment of the arsenical preparations are divisible into three classes:—

1st, Those that relate to the temperament and habit of body of the patient.

2d, The complication of the cutaneous affection with other diseases.

3d, The nature, stage, and condition of the disease of the skin itself.

1st, As regards the temperament and habit of body of the individual. It is a matter of the utmost importance in the administration of the preparation of arsenic, more so indeed than in the employment of any other remedy with which I am acquainted, to look well to the constitution and temperament of the patient to whom we are about to administer it. It will (I think, invariably) be found that arsenic, in any form, is very badly borne by individuals of a plethoric habit of body, or of a highly sanguine or sanguineo-nervous temperament; so much so, indeed, as most commonly to be inadmissible in the treatment of cutaneous diseases occurring in such persons. This, from the stimulating properties of the metal, we should, *a priori*, have been led to expect. In individuals of a ruddy complexion, with blue eyes, light or fine hair, thin delicate skins, and in whom the circulating and nervous systems are naturally very excitable, whose hearts beat and cheeks flush under the influence of even slight mental emotion, it will constantly be found that the digestive organs become so irritated, and the nervous system so excited, under the use of the arsenic, that it is impossible to employ it in any such dose as can be expected to produce a beneficial effect upon the cutaneous affection. The pulse in these cases becomes rapidly accelerated, irritation and even subacute inflammation of the gastric mucous membrane supervenes, the patient complains of

headache, and a sense of tension or weight in the forehead; and as the skin partakes of the general excitement into which the system is thrown, the cutaneous inflammation may very probably become aggravated rather than benefited by the exhibition of the remedy. It might, in some of these cases, be deemed advisable to prepare the system for the administration of the arsenicals by bleeding and purging; but, in the great majority of instances, such a procedure would not be advisable, as the habit of body to which I am alluding is one of irritability rather than of tone; one which, though readily excitable, will not bear depletion. The following cases may be mentioned in illustration of the effects of arsenic on individuals of this temperament:—

Miss E. B., æt. 22, came under my care on the 20th of December last, for an eczematous eruption on the neck, forehead, and scalp, under which she had laboured for four or five months. She is of moderate conformation, has blueish gray eyes, light brown hair, a very bright colour, and a quick though very irritable and weak pulse, varying from 84 to 90, and much accelerated when she is spoken to quickly, or when under the influence of any mental emotion. Has no dyspeptic symptoms of any consequence, nor does she suffer from any disease of the heart or lungs; but yet she complains of feeling weak and delicate, which she attributes to being much confined to the house, and prevented from taking due exercise. There are a number of irregular, yellowish gray, dry, laminated crusts on various parts of the scalp, with a scaly and furfuraceous condition of the forehead, ears, and neck, the skin of these parts being red, itching, and hot, with occasional exacerbations of the disease, and eruptions of the characteristic vesicles. Generally, however, the diseased parts had a dry furfuraceous aspect, and were not bedewed with moisture. The hair of the head was ordered to be cut off as closely as possible, and emollient fomentations and poultices to be used until the scabs were separated, and the irritation in the ears, neck, and forehead subdued. She was at the same time put upon the dilute nitric acid, with occasional slightly alterative and

aperient medicines; and the diet was ordered to be as mild and unstimulating as possible. She continued this plan of treatment until the 11th Jan., when, as no very decided improvement had taken place, it was determined to put her upon a course of Donovan's solution. I may mention that, during the whole of this time, the affected patches had been so irritable as to bear no application except such as were of a most emollient nature, and the oxide of zinc ointment; and even this seemed at times to irritate.

On the 11th of January, accordingly, she was ordered ten minims (the third of the usual dose) of the liquor of the hydriodate of arsenic and mercury three times a day. On the 15th the dose of the solution was increased to fifteen minims. On the 16th she complained of headache and lassitude, with some thirst; the old patches of the disease were much more irritable than they had previously been, and a fresh eruption of vesicles had taken place on them, as well as between the shoulders, and for some way down the back, where the affection had not before appeared. The solution was immediately ordered to be discontinued, some salines were given, and the irritation in the diseased surfaces was quieted by means of emollient applications. The nitric acid plan of treatment was then resumed, and persevered in for some little time, without permanent benefit.

As this was one of the first cases in which I had employed Donovan's solution, I was anxious to ascertain whether the irritation that had supervened during its use was attributable to the arsenic contained in it, or to some other cause. I therefore determined to try the effect of small doses of Fowler's solution. With this view I ordered her, on the 31st January, two minims of the solution of the arsenite of potassa, to be taken twice a day. On the 3d of February the same symptoms occurred that manifested themselves after the administration of Donovan's solution; there was some constitutional disturbance, with a decided exacerbation of the disease, so as to necessitate the discontinuance of the remedy. After this a number of different medicinal agents were employed, but none seemed to exercise any very permanent influence upon the complaint;

and the patient eventually left for Brighton, in the hope that change of air might benefit her.

Sophia Dewberry, æt. 23, a servant, a very healthy-looking girl, of small stature, florid complexion, dark grayish eyes, brown hair, with a quick excitable pulse, was placed under my care for pityriasis of the face and psoriasis of the lips, of between four and five years' standing. The pityriasis occupied both cheeks and the forehead, the skin of which part was somewhat reddened, and covered with furfuraceous scales. The psoriasis was confined to the lips, which were much fissured, and covered, in parts, with dark-coloured squamæ, the dark tinge arising from the oozing of blood from the rhagades in the lips when they were moved, as in laughing or eating. No cause could be assigned for the disease of the face. The general health was good, the tongue was clean, menstruation regular, and there were no dyspeptic symptoms of any kind.

As she had been submitted to a variety of treatment previous to my seeing her, without deriving any benefit, and as she was anxious, for obvious reasons, to get rid of the complaint under which she laboured, I determined to try the effect of the solution of the arsenite of potassa. She was accordingly ordered two minims of Fowler's solution twice a day, together with white precipitate ointment as a local application. On the third day of taking the arsenical, she began to complain of pain in the head, chiefly its fore part, of thirst, languor, and loss of appetite. On the following day I ordered her, as soon as I saw her, to discontinue the use of the mineral, and to take some saline medicine. She was then put upon a course of liquor potassa and tincture of cantharides, under the use of which remedies she soon got well.

These cases illustrate strikingly how ill able individuals of an excitable or sanguineo-nervous temperament are to bear even the most minute doses of arsenic. Both the patients whose cases have just been detailed were marked examples of the sanguineo-nervous temperament. In both the digestive organs were in a healthy condition, and in both the arsenic acted as too powerful a stimulant on the stomach

and nervous system, even when employed in so minute a dose as the forty-eighth or fiftieth of a grain twice a day.

2d, There are several diseases the co-existence of which with an affection of the skin should contra-indicate the employment of the preparations of arsenic. Amongst the most common of these is one that is very frequently met with in persons labouring under certain forms of chronic cutaneous disease, and of the non-existence of which it is always necessary to satisfy ourselves before prescribing arsenic in any form, as it would infallibly be much aggravated by the use of this mineral. The complaint in question is the irritative or inflammatory gastric dyspepsia; that form of indigestion which is characterized by slow and painful digestion—by a sensation of heat and oppression at the epigastrium, increased by food, by the pressure of the hand or of the clothes—by thirst, dryness of the mouth on waking, a sensation of heat and stiffness about the eyes—by a sharp pulse, rather high-coloured urine, unsound unrefreshing sleep, irritability of temper, more or less lassitude, and a costive state of the bowels; in short, by that train of symptoms that have been so well and accurately described by Dr. Todd, under the name of inflammatory gastric dyspepsia. It is more particularly necessary to be on our guard against the administration of the arsenical preparations to patients suffering from this form of indigestion, as the state of the stomach here described is very often accompanied by a papular and scaly condition of the skin, something between lichen and psoriasis, which might be thought to indicate these remedies in a peculiar manner, but which would certainly, in such a state of the system, not be benefited by their employment, whilst the irritation of the gastric mucous membrane would infallibly be much increased. It is, indeed, impossible for a patient labouring under inflammatory gastric dyspepsia to bear even the most moderate doses of the arsenical preparations, as these remedies have, in healthy individuals, a direct tendency to produce that very disease, the frequency of the occurrence of which, and the readiness with which it may be excited in persons of a san-

guine or sanguineo-nervous temperament, explains to a certain degree, no doubt, why arsenic is so badly borne by individuals of such a habit of body.

Besides irritative gastric dyspepsia, any other local inflammatory condition of the system, or the supervention of phthisis, will contra-indicate the employment of so powerfully stimulating a tonic as arsenic.

3d, One of the most important considerations to be attended to in the employment of arsenic is the kind of diseases to which it may be administered with an expectation of success; and when this has been ascertained, the particular stage of the affection at which it should be given; for, as will immediately be shewn, it may be useless, or even injurious, at one period of a complaint, but of the utmost service at another.

In order to avoid repetition I shall here omit the consideration of the particular diseases in which the employment of arsenic is contra-indicated (the list being a long one), for as I shall have occasion, in a subsequent part of this paper, to mention those in which its administration may be useful, the others will be learnt by exclusion.

With regard to the stage of a cutaneous disease in which arsenic is admissible, it may be stated, in general terms, that it only is so when these affections have assumed somewhat of a chronic inactive character, after the irritative or inflammatory condition that characterizes the earlier stages of most of them has been removed. Diseases of the skin, with but very few exceptions, are of an essentially inflammatory nature. We find the ordinary symptoms of inflammation, as it affects other tissues, present in them, more particularly during their earlier stages; the "tumor et rubor cum calore et dolore" occur to a greater or less degree in almost all of them; and the products of inflammation also, whether consisting in the effusion of serum, pus, or lymph, or in modifications of the natural structure and functions of the skin, are observable in most. This fact is of especial value in regard to the treatment of these diseases; which, indeed, consists of nothing more than the treatment of inflammation in its active or its passive forms. As long as the inflammatory action going on in

the integuments partakes of an active character, arsenic, being a powerfully stimulating tonic, is necessarily contra-indicated; and it is not until the disease has assumed a passive or atonic condition that this mineral can be tolerated; for if it be administered in the active acute stage of an affection of the skin, more particularly of one that is connected with, or dependent upon, a phlogistic condition of the system generally, it cannot fail, from the excitant properties that it has been shown to possess, in increasing the inflammatory condition that already exists. It is from the want of due attention to this point that so much difference of opinion exists as to the real value of the preparations of arsenic, not only in cutaneous affections generally, but also in the treatment of individual diseases of the skin. A medical man finds, amongst a number of remedies, arsenic strongly recommended in a particular disease, as lepra or eczema, for example; but as there is no mention made as to the period of the affection in which it should be employed, he very probably administers it whilst the complaint is still in an active inflammatory condition: the consequence of this is, that the disease being stimulated unduly, becomes aggravated in its symptoms, and the confidence of the practitioner in a very valuable remedy is shaken; whereas, had it been employed a few weeks later, the happiest results might have attended its administration. But the question naturally arises, how is the period at which arsenic is admissible to be ascertained? It cannot certainly be a matter of time, for in one case the same disease may be in a more active inflammatory condition at the end of months, or even years, than it will in another at the expiration of but a few days or weeks. In answer to this I may state, that I think it will usually be found, with sufficiently few exceptions indeed to make it a general rule, that the administration of arsenic is contra-indicated in all those cases of cutaneous disease in which topical stimulants of a mild nature, such as the ointment of the white precipitate, or of the nitrate of mercury diluted with equal parts of the spermaceti ointment, or a solution of the sulphuret of potassium in the proportion of about a drachm to the

pint, increase permanently the severity of the affection. I do not mean to imply by this that the reverse holds good, viz. that a disease in which external stimulants are employed with success should necessarily benefit by the administration of arsenicals; far from it; but I cannot recollect to mind a single case that has improved under the use of this mineral that did not bear the employment of gently stimulating ointments or lotions, provided always that the disease did not occur in a person of a very highly excitable or irritable temperament, or in one labouring under irritation of the gastric mucous membrane, or other such decidedly contra-indicating affection.

In confirmation of this I may adduce as an example that very common disease eczema, which, when in its acute stage, in which it could bear no other topical applications than the most soothing poultices and fomentations, would infallibly be greatly increased in severity by the employment of arsenic even in its most minute doses, will, at a more advanced period, when it has fallen into a passive condition, improve under the use of the mineral, at the same time that it receives the most decided benefit from the application of topical excitants, such as the white precipitate or nitrate of mercury ointments, and sulphureous baths or washes. And this is nothing more than we should *a priori* expect; for if, as I think there can be no doubt, arsenic acts as an excitant to the integumentary system, amongst the other tissues and organs, stimulating in a peculiar way the cutaneous capillaries, we cannot suppose this stimulus to be beneficial from within, unless it also is so from without.

The circumstances, then, under which the employment of arsenic in cutaneous diseases is contra-indicated having been pointed out, we shall easily arrive at a knowledge of those cases in which its administration is likely to be attended by beneficial results. It has already been shown, that the use of the preparations of this metal is exceedingly hazardous in individuals of a sanguine or sanguineo-nervous temperament and excitable habit of body, or in those who suffer from, or are peculiarly disposed to, irritative gastric dyspepsia, or any inflammatory disorder.

On the other hand, they are in most cases borne well by individuals of a somewhat phlegmatic, debilitated, or lax habit of body, more particularly if they are past the middle age, with a pale cachectic complexion, languid weak circulation, and a general want of tone about the system, acting upon such patients as powerful and useful tonics. In persons of this habit of body the diseases of the skin appear rather to be dependent upon a degree of debility or want of power in the cutaneous capillaries; and it is in these patients that the preparations of arsenic are of great service, in exciting, in a peculiar manner, a more healthy action in this class of vessels, thereby modifying or removing those morbid changes that are the results of an abnormal condition in their secretory and nutrient functions.

The diseases of the skin that are likely to be benefited by the employment of the arsenical preparations belong to very different orders in all classifications of these affections; but however widely they may be separated by artificial arrangement, they all agree in this one important respect, that they are characterized by the presence of scales or scurf; that even when they do not belong to the order *Squamæ*, they are usually but little benefitted until they arrive at that stage in which they assume a furfuraceous or scaly condition, in which state the boundary line between them and the real squamous diseases is, in very many cases, but very faintly marked. Thus, in the earlier stages of eczema, for example, arsenic is, in any form, decidedly useless, if not positively injurious; but when once this disease has fallen into that condition in which there is no longer any distinct evolution of vesicles, but, in their place, a serous fluid, which exudes at times, and dries rapidly into thin furfuraceous scales or laminae, the subjacent skin being red, glazed, dry, and more or less fissured and cracked, the use of these remedies will often be productive of the most decidedly beneficial results.

[To be continued.]

CASE OF
SCARLATINA ANGINOSA.

By CHARLES VINES, Esq.
Surgeon to the Reading Dispensary.

To the Editor of the Medical Gazette.

SIR,

SHOULD you consider the following case of sufficient interest, its early insertion in your valuable periodical will much oblige me.—I am, sir,

Your obedient servant,
CHARLES VINES.

5, Castle Street, Reading,
May 2, 1843.

February 26th, 1843, at 11 A.M. I was requested to visit Edwin Howel, æt. 12 years, of tolerably good constitution, and whose appearances were as follows: he was lying in bed on his left side, and perfectly insensible; complexion pale; features distorted; lips extremely livid; the head hot; eyelids closed; pupils insensible to light; the jaws closed, inside of mouth lined with a viscid mucous; breathing hurried and stertorous, carotids throbbled violently; extremities rather cold, hands clenched, scarcely any pulsation at the wrist; skin moist and clammy; on calling loudly into his ear he took no notice. His mother stated that he had been rather feverish for the last two days, and that yesterday he had a *rigor*; that she gave him an opening powder which operated freely this morning: the motions were green, offensive, and watery: he had passed a restless night. On taking a little tea early this morning he had difficulty in swallowing.

Treatment.—I first bled my patient in the arm to 8 ounces; the blood was dark and thick, and flowed slowly; mustard poultices were applied to the calves of the legs and soles of the feet, of these he took no notice; his head was then shaved and ten leeches applied to the temples and forehead; these bled freely, still the symptoms continued. My patient was then placed in a warm bath, where he remained about a quarter of an hour, cold water being applied to his head; during this time his arm commenced bleeding afresh, and he lost a few ounces more of blood; when in the bath slight reaction took place, but on being put to bed he relapsed into his former condition. His motions passed away at

this time involuntarily; at half-past seven in the evening, finding his symptoms worse, the breathing more oppressed, pulse at the wrist imperceptible, the carotids still acting violently, I ordered cupping on the crown of the head, and a cupping glass was applied immediately over the lambdoidal suture: at first he took no notice of the operation, but after 6 ounces of blood had been extracted, he raised his hand and endeavoured to pull off the glass, struggled to get away from his father who was supporting him, and evinced displeasure at the operation. On being again placed in bed consciousness was much more complete; he appeared to understand the questions asked, although he made no attempt to answer them; the pupils were more sensible to light; pulse at the wrist more distinct, and the symptoms altogether considerably relieved; the surface of the body was, however, cold and clammy. An enema consisting of 1 ounce Sp. Terebinth. and 2 drms. Tinct. Assafoetid. in a pint of gruel, was then administered: this he strongly objected to, endeavouring to force the instrument from him: about half the injection was retained. He was now able after considerable exertion to swallow a little liquid, and ten grains of calomel, mixed with a little sugar, were placed in his mouth: this, with the aid of some tea, passed into the stomach. A liniment composed of croton oil, ammonia and soap liniment, was then rubbed freely over the outside of the throat.

At half-past 9 P.M. the countenance was more calm and natural. The lips had lost their livid hue; the carotids comparatively quiet; pulse at wrist quick, but much more distinct; extremities warm, and he expressed by signs that he was better, but still swallowed with great difficulty. I ordered a tea-spoonful of gruel to be placed in his mouth occasionally, and a fourth part of the following every two or three hours.

R Liq. Ant. Pot. Tart. 3j.; Liq. Ammon. Ac. ʒss.; Sp. Æth. Nit. 3j.; Aq. Menth. Sat. ad. ʒiij. M. ft. Mist.

27th, 9 A.M.—My patient had passed a restless night; had been delirious; bowels had not acted; head a little hotter than natural; surface of body generally warm; pulse extremely quick and small; complained much of his throat, and had a great dread of taking

any thing into his mouth; the tonsils, tongue, lining membrane of mouth and fauces, very red and swollen.

To continue the mixture, and to take the following powders.

R. Ant. Potassio-Tart. gr. $\frac{1}{4}$; Hydrarg. Chlorid. gr. ij.; Pulv. Trag. Co. gr. iij.; M. ft. Pulvis, 4ta. q. h.

9 P.M.—Reaction more fully established, but deglutition still very difficult; bowels had been open twice.

A blister to be applied to the throat, and the medicines continued.

28th.—Had slept a little during the night; blister had drawn well; the throat slightly relieved; gums affected by the calomel; countenance calm; no pain except from the throat; pulse a little fuller.

Ordered a chloride of soda solution for the mouth. To discontinue the calomel.

March 1st.—My patient had slept much better; deglutition more easy, and consequently able to take more nourishment; pulse fuller, but soft; bowels confined.

To continue the mixture, with the addition of 2 drs. of sulphate of magnesia.

In the evening a roseolar appearance shewed itself on the hands and arms, also slightly on the face.

2d, 9 A.M.—Had slept several hours during the night; able to speak distinctly; expressed himself much better; throat almost free from pain; roseolar appearance of skin more distinct; pulse tolerably full and soft; bowels were well open during the day.

3d.—Had slept nearly all night; roseolar blush of skin had disappeared; could swallow almost as well as usual. From this period my patient gradually progressed towards recovery, and in the course of a fortnight was quite restored to health.

OBSERVATIONS.—The history of this case, in connection with others lately occurring in my practice, has suggested the few following observations. In the first place, what was the condition of the patient here described? I would answer, a state of coma or asphyxia, that kind of coma induced by unhealthy non-arterialized blood circulating in the brain. The brain had become narcotized, unfitted to perform its peculiar function. And the heart, not receiving its usual supply of ner-

vous stimulus, nor a due share of arterial or oxygenized blood, was depressed in its action; thus vitality weakened would soon have ceased altogether. Superadded to this condition must have been that of arterial excitement, evidenced by the throbbing of the carotids, and thus, according to Dr. Kellie, the overcharged cerebral arteries, compressing their corresponding veins, would tend to impede still further the circulation within the cranium, and consequently of the vascular system generally. Hence the whole system was in a state of congestion, each vital organ participating in this depressed condition of the grand nervous centre.

To what cause, then, are we to attribute this comatose or asphyxiated condition? To an inflammatory condition of the throat, viz. effusion into the cellular membrane of the throat and fauces causing obstruction to the entrance of air into the lungs (apnoea); or to arterial excitement impeding the vascular circulation within the brain? I am inclined to suppose by a combination of the two causes. From the history of the case, the rigor which preceded the difficulty of swallowing, and the throbbing of the carotids, there can be no doubt as to the arterial excitement; and we have equal evidence that there was obstruction of the throat. Those who contend for the action of a specific poison in cases of fever might say that the symptoms were attributable to this agent exerting a depressing influence on the brain and nervous system generally; but I think that the treatment of the case disproves such a notion. Now blood-letting, in the first instance, proved to be the only efficient remedy; but a quantity of blood taken from the arm and temples produced no effect. The warm bath effected only slight reaction, followed by more decided collapse; but on the abstraction of a few ounces of blood from the vertex of the head, the brain was instantly relieved. The blood was extracted opposite the upper angle of the occipital bone, just at the junction of the sagittal and lambdoidal sutures. The longitudinal sinus traversing the upper surface of the brain in this situation communicates freely with the cranial bones, and the quick removal of blood in this situation tended to relieve the vessels immediately in the neighbourhood. A stimulating injec-

tion then served to rouse the central organs, and, by a reflex action on the nervous system, materially aided to rally the sinking powers. Reaction having been once established, no further stimulants were requisite; in fact they were contraindicated by an inflammatory tendency in the system.

It is evident, from the case in question, that the pulse afforded no criterion as to the necessity for the abstraction of blood. When the patient was first seen his pulse was scarcely perceptible. To have given stimulants, with the idea of waiting till signs of reaction manifested themselves, would have been dangerous in the highest degree, since the proximate source of the depressed circulation existed in the brain: the removal of blood, then, in order to relieve the oppressed state of the cerebral organ, afforded the patient the only chance of recovery.

Other severe cases of head affection having, as I before observed, lately occurred to me, I hope shortly to introduce them to your notice.

REMARKS

ON SOME

CRITICISMS ON A LATE REVIEW IN THE BRITISH AND FOREIGN MEDICAL REVIEW.

BY DR. GOLDING BIRD.

“Folget nun des meisters worten
Was er sagt, gilt aller orten.
Nicht die Form zeigt euch die wahrheit,
Nicht der Stoff führt euch zur klarheit,
Müßet beide gleich behandeln,
Wollt ihr nicht im Irrthum wandeln.”

IN a late number of the *Lancet*, a letter has been published by Mr. Ansell, in which he has endeavoured to invalidate the correctness of the observations made by the author of an able review of Dr. B. Jones's work on Calculus and Gout, in the last number of the *British and Foreign Medical Review*. As the arguments to which Mr. Ansell particularly takes exception are the same as those which I brought forward in my lectures at Guy's Hospital, and which were published in this journal, I feel myself called upon to take some public notice of the strictures made upon them. In doing this, I shall content myself with alluding strictly to that portion of Professor Liebig's views to which Mr. Ansell has alluded; not

with a view of exciting an useless discussion, but for the purpose of shewing that he has not succeeded in proving the “futility of the objection” brought forward by the reviewer.

The opinion that urea and uric acid are formed from the destructive assimilation of effete animal tissues, advanced by Dr. Prout, and brought forward by Liebig in his late work, is now conventionally admitted. In fact, there can scarcely be a reasonable doubt on the correctness of this view. Liebig has gone further than this, and has laid it down as an axiom, that urea and uric acid are produced by oxygenation of tissues, the latter being produced when too little oxygen is present to allow the former to be generated, and hence that in reptiles slowly respiring, and consequently but little exposed to the influence of oxygen, an abundance of uric acid is excreted in the urine, which is replaced by urea, as we ascend the scale of animal life, until, in the warm-blooded carnivoræ, deposits of uric acid are unknown. I endeavoured to shew, in one of my lectures, the unsatisfactory nature of this sweeping generalization, by the case of birds, the semi-solid urine of many of which consists of a large proportion of uric acid. This objection, so far from being met by Mr. Ansell, is, in fact, avoided in defending Liebig's statement, that the ulterior conversion of animal matter into urea may take place alike at the surface of the metamorphosed tissue, and in the secreting organ,—a proposition of very little consequence, as it neither admits of proof or refutation. The winged inhabitants of the South American rocks have covered these islets with a thick layer of guano (urate and oxalate of ammonia essentially), in spite of their possessing the very conditions which Liebig assumes ought to prevent the formation of uric acid; for they possess higher temperature, more active respiration, and a greater proportionate number of blood corpuscles*, than any other class of animals; they breathe the oxygen of the air with the aqueous vapour exhaling from the ocean surrounding their maritime resting-places; they, for any thing

* Or, in Liebig's own words, “Die Temperatur des Blutes ist im Allgemeinen bei den Vögeln höher, als bei den anderen Thierklassen, ebenso haben die Vögel die meisten Blutkörperchen.”
HANDWORTERBUCH, B. I. s. 92.

that is known to the contrary, drink water enough for all the conditions required by the theory, or rather hypothesis, of Liebig; and yet these sea birds, in common with many of their inland allies, pertinaciously oppose the dogma of the professor of Giessen, by dropping from their cloacæ urate of ammonia.

Mr. Ancell's criticisms are most pointedly levelled at certain deductions drawn from a table which has been quoted by the reviewer on my authority, and which was first published in my lectures as giving a view of some of M. Becquerel's clinical observations. This table, with the exception of a slight numeric error, which has been pointed out, is perfectly correct, and the numbers it contains were carefully calculated by myself. The intention with which I exhibited this table to my pupils was to demonstrate to them that the ratio between inflammatory action, or excessive oxygenation, and the disappearance of uric acid laid down by Liebig as a law, was not in accordance with recorded experience. In the cases of well-marked chlorosis, where every symptom, and even the very state of the blood, proves that oxygenation, in the view assumed by Liebig, must be most imperfect, and therefore where we ought to have excess of uric acid, we have nothing of the kind: yet no one can deny that metamorphosis of tissue goes on in this case. Mr. Ancell ingeniously attempts to explain the difficulty by alluding to the fact that blood-corpuscles are decidedly deficient in this affection; and yet, a page further on, this gentleman uses the very same argument to explain the presence of uric deposits in inflammatory diseases. Thus the diminution of red particles (carriers of oxygen of Liebig) is used at once to explain the partial absence of uric acid in anæmia, and its excess in phlegmasiæ. I think it is not too much to denounce such ancipital arguments as utterly worthless, and destitute of any thing like a true scientific character. Let us, however, for a moment, take two cases, one of excessive pulmonary emphysema, and the other of acute hepatitis; being two of those quoted in the table. In the former, where the lung has undergone a change almost approaching to that of the turtle, and where the cold surface, the leaden lips, all attest imperfect oxygenation;

and in the latter, where the intense inflammatory fever present shows this process, according to Liebig's interpretation of the phenomena of inflammation*, to be carried on in excess. In the latter, therefore, uric acid should nearly disappear from the urine, and in the former be in excess; whilst the very reverse of this really occurs. But even if these cases did really bear out Liebig's view, how can a diminution of red particles in both cases explain such different effects?

We have an excellent illustration of the effects of extending a theory to its utmost limits, in the remarks on the urine of phthisis, which is declared to be a disease of excessive oxygenation, and therefore one in which uric acid deposits can scarcely exist. This is stated directly by Dr. Jones (p. 11), and distinctly implied by Professor Liebig (p. 137). In opposition to this, I brought forward facts which appeared to me sufficient to shew that this dogma, founded on reasoning in the laboratory, was opposed to actual experience so far as it had extended. Mr. Ancell again endeavours to explain this discrepancy between fact and theory by means of the blood-corpuscles, which, being diminished in phthisis, ought to produce an excess of uric acid. Liebig, however, states that there ought to be nothing of the kind; and thus the Professor and Mr. Ancell are opposed. In justice to the latter gentleman, however, we must not forget that he appears to be by no means satisfied with the piece of special pleading regarding the blood-discs in this disease, as explaining the existence of what Liebig denies, and in another part of his criticisms he inquires whether uric acid may not be in excess late in the disease only.

In commenting on another portion of the review, Mr. Ancell declares that the statement there made, that 100 grains of azotised solids are daily excreted by the skin, is advanced "most fallaciously." I am ignorant on what grounds this bold charge is hazarded; certainly on no facts at present before the profession. In my lecture I gave the results of the well-known experi-

* "In consequence of the acceleration of the circulation in the state of fever, a greater amount of arterial blood, and consequently of oxygen, is conveyed to the diseased parts as well as to all other parts."—LIEBIG, p. 256.

ments of Seguin and Anselmino, and shewed that in 24 hours the skin exhaled:—

Organic matter	107·47 grains
Saline matter .	81·92 "
Volatile matter	15650·61 "
<hr/>	
15840.	

These 107·47 grains of organic matter are as rich in nitrogen as many other effete products of vital chemistry, and closely resemble the *extrait de viande* of Berzelius. I have in more than one instance detected distinct evidence of the presence of urea in it. Is it, then, just to denounce the statement that azotised matter is exhaled from the skin, as "most fallacious?"

Throughout the whole of his criticisms, the varying quantity of blood-corpuscles, or carriers of oxygen, in the blood, constitutes Mr. Ancell's great *cheval de bataille*. The very grounds of his defence of Liebig's hypothesis on this point are debateable; even Andral's and Lecanu's analyses, to which he refers, are not satisfactory. Their mode of determining the preparation of blood-discs is by no means free from error; in fact, we know of no means at present of doing so with any amount of accuracy; and were Mr. Ancell more practically acquainted with the difficulties surrounding quantitative analyses of blood, he would learn to be very cautious before he founded arguments of this importance upon them. The elegant and luminous researches of Dr. Rees on the anatomical and physical properties of the blood-corpuscle have thrown much light on this difficult problem in zoochemistry (Guy's Reports, April 1843).

To turn, however, more particularly to Liebig's doctrine, that blood-corpuscles are carriers of oxygen: on what proof does this rest? All the few facts he has advanced in support of this hypothesis admit of other explanations. He has, indeed, declared the iron to exist in venous blood as protoxide, and in arterial as sesquioxide: where, again, I may venture to inquire, is the proof of this statement? We look in vain for one, but find indeed the following sentence: "Let us now assume that the iron in venous blood is in the state of protoxide," p. 273. Liebig then goes on to develop his hypothesis of respiration, by grafting this, a pure

assumption, which few will feel inclined to grant, on an old and familiar theory of intra-combustion. It has not, indeed, even been proved that iron exists in blood-corpuscles as an oxide at all; there are many reasons for doubting it; if it does not exist in a metallic state, it in all probability forms a binary compound, analogous to an haloid combination. If we refer to Liebig's mode of examining the blood, every one acquainted with the structure of the corpuscle, especially since Dr. Rees' observations, must be struck with its utter unfitness to give any thing like even a distant approach to the truth. He directs dried blood, or red particles which have been separated by subsidence (*eingetrocknetes Blut, oder Albumin-Blut-roth*), to be mixed with strong sulphuric acid*; a paste is thus formed, which deliquesces in the air. It is unnecessary to pursue the process further, as this first step is sufficient to prevent our learning in what state the iron really exists in the blood-corpuscle, or indeed any thing else about it, as the disorganizing influence of the corrosive acid employed must be sufficient to utterly change the nature of the very body we are endeavouring to investigate. It is like attempting to study the anatomy of an animal by crushing it in a mortar before we commence its dissection. One of the most excellent chemists of the day, and one who has worked well and successfully in the path of organic chemistry under the auspices of Dumas, Professor Kane, of Dublin, differs altogether from the assumption of Liebig; he has declared that, "with the knowledge we now possess of hematosine in its pure form, we must consider the iron to be an integral part of its organic constitution, as sulphur is in albumen, or arsenic in alkarsin; and the opinion of its being oxidized, and combined with the two organic elements as a kind of salt, can no longer be supported†."

With every honest desire to do justice to the high and acknowledged talent of Professor Liebig, I feel that it must be regretted that he has left the path of pure chemistry, in which he was really a blazing luminary, to ven-

* Handwörterbuch der reinen und angewandten Chemie, b. i. § 884.

† Elements of Chemistry, 1841, p. 1147.

ture in the field of pathology unsupported by experience. In his whole work not a single case is alluded to, nor reference made to clinical experience in support of a single view. He seems to look upon the animal organism as a mere machine, in which the ordinary physical laws obtain as completely as when acting on dead and inert matter; and this has led to his making often loosely expressed statements which astonish us. I would, in illustration, refer to but two instances in which he has applied the phenomenon of exosmosis to the body, in a manner which, had any one but the professor of Giessen uttered them, had brought down on the devoted head of the writer all the gall of the critic; and yet, in all the so-called reviews of Liebig's work, they have scarcely been alluded to. He states that death often occurs by drinking "creaming" wines, containing loosely combined carbonic acid, and thus explains the cause of death. "The carbonic acid which is disengaged penetrates through the parietes of the stomach! through the diaphragm!! and through all the intervening membranes of the lungs, out of which it displaces the atmospheric air!!! The patient dies with all the symptoms of asphyxia caused by an irrespirable gas; and the surest proof of the presence of carbonic acid in the lungs is the fact that the inhalation of ammonia is recognised as the best antidote against this kind of poisoning."—p. 116. The absurdity of the first part of this explanation is sufficiently apparent: where is the proof that the carbonic acid can thus penetrate all the living tissues alluded to? The action of ammonia affords none. A less brilliant interpreter of symptoms than Liebig would be content with a different explanation. A German toper imbibes his ill-fermented *federweisse wein*, and succumbs from the influence of his potation on the nervous system; in other words, is very drunk. The ammonia held to his nostrils exerts its well-known effect in intoxication, and gives some relief to symptoms which, from their cerebral character, might by possibility, by an unpractised eye, be mistaken for asphyxia. If Liebig's explanation were correct, ought not these cases of what he has called *asphyxia* to occur in this country among our

summer imbibers of ginger-beer, spruce-beer, or soda-water? It is well known they do not, for the simple reason that they cannot produce intoxication, which the ill-fermented wine will readily do.

Again, in alluding to the gases exhaled from the lungs, Professor Liebig has stated that "the presence of membranes offers not the slightest obstacle to their passing directly into the cavity of the chest."—p. 117. A statement more opposed to fact can scarcely be conceived. We know that the pleura and fibrous capsule (?) of the lung completely prevent the escape of air into the chest. If this were not the case—if nature in her wisdom had not been a better physiologist than the professor—life would be in daily danger from pneumo-thorax. Where are the cases recorded in which air has escaped from the lung into the chest during life, without breach of surface? I might point out other instances in which Liebig has allowed his brilliant imagination to outrun sober experience. I have quoted these to show that the dogmata he has laid down are not to be regarded as infallible, nor that all who venture to differ from him are to be charged with bringing forward "futile," "unfounded," or "most fallacious" statements, especially at a time when Dumas and Boussingault, in France, have severely shaken some even of his more strictly chemical inductions; and when a talented chemist of our own country, Dr. Kemp, of Cambridge, has shown that the composition of bile, and the formula he has assumed as the base of his reasoning on the products of the chemistry of life, are absolutely erroneous. It is not impossible that Liebig, high as his name must ever rank in chemistry, may one day regret that he did not apply his pathology to the test of experience, 'ere he gave it to the world.

—Heisse Magister, heisse Doctor gar,
Und ziehe schon an die zehen Jahr;
Herauf, herab und quer und krumm,
Meine schuler an der nase herum,
Und sehe, dass wir nichts wissen Kennen!
Das will mir schier das herz verbrennen.

FAUST.

In conclusion, if Mr. Ancell will apply the industry and talent which so characterize him by helping those who are, and have been long working at the bedside, he will (if he will excuse

the remark) confer a greater boon on the profession to which we belong, than by acting as a commentator or interpreter of dogmata which now want not a logical but an experimental criticism.

MEDICAL GAZETTE.

Friday, May 12, 1843.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

LEGISLATION IN MEDICINE.

IN a late number we alluded to the fact that professional men are divided into two great natural orders; those, namely, who can afford to wait for practice, and those who cannot. We showed, also, that the time and means at the disposal of a student influenced his professional acquirements and his social position.

We should be heartily glad if every man who practises medicine or surgery in the British dominions belonged to the first division; but we fear it is scarcely possible that it should be so.

Those who have seen what the most facetious of churchmen has said of the attempt to establish a body of clergy, who, for £150 a year, should be patterns of good taste and gentlemanly bearing, as well as of all the cardinal virtues, will have no difficulty in applying the satire, *mutatis mutandis*, to the members of our own less dignified calling.

For many reasons, some obvious, others not so evident, ours is of all the professions by far the least followed by men of independent fortune. We have, as a class, no defined social position, such as is occupied by the naval and military officer, the clergyman, and the lawyer. We fill hardly any public offices, and there are no provisions for our studious youth, like those which the church has for her "poor scholars," or the honorary commissions in the two warlike services.

This undefined social position among a nation only less sensitive than

ON NEW PERCUSSING INSTRUMENTS FOR INVESTIGATING DISEASES OF THE CHEST.

To the Editor of the Medical Gazette.

SIR,

You were kind enough to insert in the last volume of the MEDICAL GAZETTE, page 379, an account, with an engraving, of a new percussing instrument, termed an echometer, which I invented for the purpose of producing uniform sounds. I beg now to introduce to your notice a modification of that one, involving the same principle. The present instrument, which was made by Messrs. Philp and Whicker, of St. James's Street, at my request, is much more convenient than the other, in consequence of being greatly reduced in size, and elicits louder sounds.

The plessimeter, surrounded by a ring, acts on a swivel. The instrument should be pressed upon the chest by the fore finger and thumb of the left hand, while the percussor, raised by the fore finger and thumb of the right hand, is propelled by a circular spring. The elevation of the percussor is regulated by a screw at the top of the regulator, which passes over the spring.

I am, sir,

Your obedient servant,

C. J. B. ALDIS, M.D.

Lecturer on Medicine at the Charlotte
Street School.

13, Old Burlington Street,
May 5, 1843.

their American kinsmen,—the various and almost imperceptible gradations which separate the titled physician from the obscure shopkeeper,—the disposition to cultivate professional good fellowship, struggling with the broad facts of social and educational inequality, contribute, no doubt, to produce that *gêne* and want of ease so often apparent amongst our brethren. But to the same conditions is no doubt owing much of the circumspect behaviour and quiet conduct which characterize us in general, and to which, when at any time the exceptions are numerous, they are to be attributed to peculiar circumstances—such as the recent superabundance of young, ill-educated, and undisciplined members.

In speculating on the expected bill for medical reform, it will occur to some, and may prevent disappointment to remind others, that the duties, as well as the interests of the government, are totally different from those of the profession.

The minister is bound, it would appear—for we leave out the doctrine of total non-interference, the *laissez faire* system in its maturity—to insist on a minimum of qualification for those who are liable to be consulted on the bodily ailments of their fellow subjects, without the possession of which no person shall be allowed to undertake the cure of disease. He is bound to make inquiry of those best informed on the subject as to how much it is absolutely requisite to demand for this purpose; and to appoint a competent body to examine candidates and grant licenses. Having done this, his duty to the public is performed.

As a matter of detail it may be expedient to consider whether the burthen and the privilege of enforcing the law against offenders should be committed to the licensing body or to the public

prosecutor. Many think the government should undertake the punishment and the putting down of quackery. We are not of this opinion; but think that the government having obtained the proper information as to the qualifications required for a license to practise medicine, and having made it penal to practise without a license, must leave all cases of contumacy against the licensing body to be punished under the general law against such offences, all malapraxis amongst those who are licensed being punishable according to the damage done in the particular case to person or property.

This, then, or something of this kind, Sir James Graham seems disposed to do. But we do not live in a country, nor under a form of government, where a principle can be planned and laid down to have laws framed upon it and fitted to it: our materials for legislation are not so ductile. The ancient structure of our constitution is not, like an Athenian temple, formed of blocks squared and carved beforehand, but rather like the Cyclopean walls of heroic and half-fabulous ages. The huge fragments are carefully adjusted, indeed massive and permanent, but most irregular; each adopted only because found fitting, those having been rejected which were intractable. In later times, certainly, we find fragments of all sizes, shapes, and qualities, ruins of things new and old, thrown together into a soft and yielding cement. Of this cheap and tractable material, this *opus incertum*, modern utilitarianism finds it convenient to make most of its improvements.

The duty of the profession, on the other hand, seems to be to raise its own dignity and its value in the eyes of the state; to shew that it duly performs the work entrusted to its care, and deserves the privileges or the distinctions, the

honours or the profits, which are considered to be its due. For this purpose it has to exact from its members much higher qualifications than those fixed by the state as a minimum; it has to create honours and rewards within its own jurisdiction, or to recommend the most deserving of its members to external patronage.

Now that the bitterness of encroachment and resistance has in great measure subsided—now that each party is conscious that much requires change, and that much must be left—now that each, sobered by time and reflection,

“Can the warmest friend reprove,
And bear to praise the fiercest foe,”

we may see, by experience of the past, how much may be left to be worked out by the moral energies of our profession, and how little need be done in aid of this by legislative interference. The Worshipful Society of Apothecaries were simply entrusted with the privilege of granting licenses to practise pharmacy to those who were not already in practice, and they have gradually raised their standard of qualification, which, before 1815, was at least as low as that of the counter-practice of the druggist, till it embraces nearly every known department of the science of medicine, and by far the greater number of its licentiates are also members of the College of Surgeons. There can be no greater proof of the disjointed state of matters than that the fact of membership with this highly educated body disqualifies for the license of the College of Physicians, and for a seat at the Council of the College of Surgeons. Wherein, however, consists the disqualification? not in the supposition that the member is unable to hold the amount of knowledge required of him as a physician, or a councilman, in addition to what he has been obliged to know as an apothecary—not, in fact, that

———“Still the wonder grew,
How one small head could carry all he knew :”

for the mere act of being disfranchised at once removes his disability. The real cause, we suspect, was a not unrighteous fear of contamination from the shop; so long as the apothecary continues a dealer in drugs, so long is he in a different category from those who abstain from such a source of profit. The surgeon with his apparatus of various kinds, his plasters, his bandages, his splints, is not a whit less mechanical in many of his details, but he has contrived totally to escape the slough in which his neighbour is fixed.

The teeth and the eyes of Englishmen are not that we know of under the especial protection of government. It is well known that dentists and oculists have flourished here for centuries, *vixere ante Agamemnona fortes*, practising without either let or license, on all who chose to submit to them. There may be some obsolete act for punishing all operators of this class; but at all events there is no college or society disposed to undertake the prosecution.

Dentistry, then, like druggistry, has grown up to its present flourishing and useful state outside the pale of all the corporations, and in spite of their laws. The art once cultivated has voluntarily sought the aid of science, scientific practice and preliminary studies have raised its professors to fortune and eminence, and it is not too much to believe that, at no very distant period, dentists who are not surgeons will be rare and despised exceptions to a general rule. But it may well be doubted whether if any even of our most eminent dentists thought it worth their while to derive a profit from some well-known shop near St. Martin's Lane, the College of Surgeons would consider them quite creditable members of their body. Much in the same way does uniting the trade of a druggist with the practice of

medicine degrade the general practitioner, and we cannot but think that any arrangement amongst the members of a profession which draws a distinction between those who trust exclusively to an art or a science, and those who derive part of their gains from trade, do good service in raising and upholding the standard of professional character.

NOTICE RELATIVE TO RETURNS OF "CAUSES OF DEATH."

To the Editor of the Medical Gazette.

SIR,

I SHALL feel much obliged if you will inform the readers of the MEDICAL GAZETTE that the Registrar General has recently given the following direction to the registrars of deaths:—

"When the information given to you by the medical attendants upon deceased persons, respecting the 'cause of death,' contains also a statement of the *duration of the fatal diseases*, or is accompanied by the memorandum (*p. mortem*) denoting that the nature of the causes of death had been ascertained or verified by a *post-mortem* examination, you will not fail to enter these statements in the column of the register, headed 'Cause of Death'."

It is desirable on many accounts that the laws respecting the duration of diseases should be ascertained, and this will afford the medical profession an opportunity of entering on permanent record a sufficient number of observations for determining those laws, as well as the laws of mortality.

With regard to the registration of the "causes of death," it has been found the most convenient and satisfactory course for the medical attendant to leave a written certificate with the friends of the deceased person, to be placed in the hands of the registrar.

The registrar is directed to ask the informant whether any written statement of the cause of death has been left by the medical attendant, but the relatives, from the natural distraction of grief, or ignorant of its scientific importance, are apt to forget the medical certificate, unless the medical attendant take the trouble to state that it will be required, and place it in their hands.

If the medical profession needed any stimulus to induce them to contribute to the promotion of medical science, or to the discovery and consequent removal of the causes

of untimely death, it will be found in the following considerations, to which the Registrar General has adverted in his last Report:—"I hope that the members of the medical profession, who have hitherto given their aid, will cordially assist in carrying out this national registration of the causes of death, as they alone are able to give a correct statement of the nature of the fatal diseases; and to them, more than to the members of any other profession, must be apparent the vast importance of thus collecting accurate materials for advancing the science of vital statistics."

Copies of the "Statistical Nosology, with notes and observations for the use of those who return the causes of death," may be procured by any medical practitioner upon application (verbal or written) at the General Register Office.—I have the honour to be, sir,

Your obedient servant,
WILLIAM FARR.

CAUSES OF DEATH AFTER OPERATIONS IN THE LONDON HOSPITALS.

To the Editor of the Medical Gazette.

SIR,

IN an essay published in your journal of to-day, by Mr. T. Wilkinson King, a remark appears relative to some of my observations upon "the causes of death after operations and injuries in London hospitals," recorded in the last number of the Guy's Hospital Reports, which I cannot permit to pass unnoticed.

At page 194 of the GAZETTE, Mr. King observes, after alluding to my remarks, "These principles have been long taught at Guy's, and the facts on which they are based run through a series of thirty or forty large volumes of museum manuscripts, which are not merely records of common facts." And again, "A tabular analysis of the whole, for more than twenty years, kept up since I was a pupil, renders the whole available almost at a glance. Dr. C.'s exposition is principally based upon my own autopsy-histories." Now, sir, I must beg to observe, that Mr. King is totally in error in advancing the unfounded assumption that the principles which I have adduced are based either upon his or upon any other person's autopsy-histories. I have stated in my paper in the Reports, and I now repeat the affirmation, that the deductions which I have there drawn are wholly based upon my own observations and inquiries, pursued in the wards and dead-house of Guy's Hospital during the last eight years; every principle which I have announced in that paper as my

own is founded upon cases which I have myself seen and carefully investigated. I first gave a full exposition of the principles which form the ground-work of my last essay, in a paper (entitled, "Remarks on Asthenic Inflammations of Serous Membranes,") read before the Pupils' Physical Society of Guy's Hospital, in December 1837—a period at which, I apprehend, a very large proportion of Mr. King's autopsy-histories had not been recorded in the museum books. In that paper, as well as in the essay lately published in the Reports (note to page 91), I quoted an observation made by Dr. Hodgkin about fourteen years since, to the effect that he had observed mottling of the kidneys in patients who had sunk after operations and injuries. I had remarked the same fact before meeting with Dr. Hodgkin's observation; but I of course thought it right to append this important anticipatory remark to each of my essays. I have also expressly quoted, in my memoir in the Reports (page 97), the observation put forth by Mr. Key, in his lectures, "that he has scarcely ever seen a fatal case of lithotomy in which there was not discovered organic disease of the abdominal viscera, and more especially of the kidneys." I was first made aware of this some days after I had received the proof sheets of my paper from the printer. Beyond this I am perfectly willing to repeat, however unnecessarily, an admission which I have already made, of my obligation to the post-mortem registers for the *confirmation* of the views which I had previously committed to writing, and had advanced upon several occasions in the discussions of the societies attached to Guy's Hospital, long before I had recourse to those registers, which I looked upon merely as the most ample collection of cases to which I could refer in finally testing the correctness of my opinions before submitting them to the profession. In my essay in the Reports, I have therefore expressly stated (pp. 88, 89), that "for the purpose of confirming the observations which I had made at Guy's Hospital for several years past, I carefully examined the accounts of all the cases where death occurred from the secondary effects of operations, &c., which have been entered in the post-mortem registers of the museum during the last fifteen years." I have then given tables, in which the results of that examination are stated. I conceived it fully sufficient to mention, that these confirmatory tables were drawn from the above source, without dwelling upon the fact (often previously announced in print, and probably known to most professional readers), that these registers have been principally kept by Dr. Hodgkin and Mr. King. With respect to the "tabular analysis" of the post-mor-

tem registers by Mr. King, I must state that I did not find it very available in the above examination of those records; I certainly referred to it as an index, which it simply is, in looking over some of Dr. Hodgkin's inspections; but I preferred, in every instance, to trust to my own perusal of the cases.

I therefore beg to repeat that I am not in the slightest degree indebted to the reports or observations of Mr. King for the *basis* of any one of the results which I have advanced in my essay published in the April number of the Guy's Hospital Reports; but I freely acknowledge, as I have already done in that essay, the valuable *confirmation* which my views have received in the plain details of cadaveric inspections, by Dr. Hodgkin, Mr. King, and Mr. Roderick, contained in the museum registers of Guy's Hospital.—I have the honour to be, sir,

Your obedient servant,

NORMAN CHEVERS, M.D.

Frith Street, Soho Square,
May 5, 1843.

DIABETES.

ERROR IN TRANSLATION.

To the Editor of the Medical Gazette.

SIR,

IN the number of your valuable journal for the 21st of April ult., I observe that Dr. Percy, in his interesting case of diabetes, has called my attention to the following error in my translation of Dr. Bell's Essay on Diabetes, at page 49:—"By injecting into the vessels a solution of cane sugar, we do not find that the sugar passes into the blood or urine, but by the pulmonary transpiration. We know that cane sugar, taken into the stomach, in whatever quantity, never passes by the urine." By referring to Krimer's experiments, detailed in Horn's Archiv für Medizinisch Erfahrung, 1818, the above will be found to be an exact translation of the original paragraph, at page 536, b. ii. of that work. However, the author's meaning will, I think, be rendered more intelligible by being thus stated:—"If a solution of cane sugar be injected into the veins, a very short time suffices for its complete disappearance from the blood; it does not pass into the urine, but is eliminated by the pulmonary transpiration."

If you will allow me to make this correction through the medium of your columns, you will greatly oblige me, and I am, sir,

Your obedient servant,

ALFRED MARKWICK.

North Brixton, May 5, 1843.

VIREY'S OBJECTIONS TO LIEBIG'S THEORY

OF THE USES OF RESPIRATION
AND OF FOOD.

ERESIE maintains that the chief use of the food is to supply carbon and hydrogen, which, uniting with the oxygen absorbed from the air, give rise to the generation of animal heat. He consequently holds that there is a certain fixed relation between the amount of food consumed, and the quantity of carbon and hydrogen thrown off at the lungs. M. Virey opposes this theory, as contrary to common observation, as, even though it be allowed to be applicable to mammalia, birds, and reptiles, it is by no means to those animals which respire by means of branchiæ. Thus all animals with branchiæ consume but little oxygen, comparatively speaking, and yet many of them devour very great quantities of food. Even the largest and most voracious of the reptiles, as the alligators, crocodiles, &c. which devour enormous quantities of food, under a burning climate, too, respire feebly with their vesicular lungs, and consume but little oxygen.

Fishes, whose blood is but imperfectly oxygenated by the branchial apparatus, are perhaps among the most voracious of animals, and yet, according to Liebig's theory, they ought to eat little, because they consume little oxygen.

The same holds true of the Mollusca. The cuttle-fish, *buccinum*, *strombus*, *murex*, &c. grow to a large size, but their respiration is very imperfect, and yet they are great flesh-eaters. The Crustacea, again, as the crabs, lobsters, &c. grow rapidly, because they are great eaters, but their branchial apparatus is not fitted to consume much oxygen.

In all these animals assimilation takes place very rapidly, notwithstanding their feeble respiratory powers; and they are, besides, by no means deficient in activity or muscular powers, though their flesh be but feebly azotized or animalized, and their blood is always cold.

If it be one of the characters of vitality, that the more perfect this principle is, the greater is the number of germs, or eggs, or foetuses produced, then, quite contrary to Liebig's theory, the number of germs produced is in the inverse ratio of the perfection of the respiratory functions. Fishes and mollusca deposit their spawn or eggs by millions; but the mammalia, and even the birds, whose respiratory functions are the most perfect, are in this respect infinitely behind these. On the other hand, it is seen that the number of germs or eggs is

rather proportioned to the assimilation received; for the amount of food taken is not proportioned to the respiration in the animal kingdom.

M. Virey therefore concludes, that the vital force, or central nervous energy, has more to do with the production of animal heat than the consumption of carbon at the lungs, and this for three special reasons:—1st, Because a fecundated egg resists a freezing temperature longer than one which has not been fecundated. 2d, That a hibernating insect, reptile, or animal, or even trees during winter, by the sole influence of a vital power, resist a freezing temperature, whereas the same animals, if dead, would be instantly frozen. 3d, That many mammalia and birds keep themselves warm even in the most rigorous winters under the Pole, not in consequence of a greater amount of oxygen consumed, nor by a greater amount of muscular activity, but in consequence of a more abundant, highly azotized, or animalized nourishment. — *Journ. de Pharm.*, and *American Journal*.

JULES GUERIN ON STRABISMUS.

M. JULES GUERIN has published a second Memoir on Strabismus, devoted to a rational and experimental inquiry into the distinction between the optical and the mechanical forms of the disorder; a former memoir, published in the same journal the 3d April, 1841, having treated principally of the mechanical or primitively muscular form.

Optical strabismus, the principal subject of the present paper, the author defines as a consecutive of secondarily muscular deviation of the eye, consequent on a disjunction of the axis of vision and the axis of the eye. This disjunction may be produced in three ways: 1st, from an obstacle to the passage of visual axis along the course of the ocular axis; 2dly, by a change of relation in the refracting media without alteration of their transparency, or 3dly, by an insensibility of the retina at the proper point for the reception of luminous rays. The first is characterised by the squint existing only while the patient is looking at an object. In these cases the two visual axes, though no longer concurring with the ocular axes, converge towards one point.

A squint, then, existing only during active or intentional vision, cannot depend on permanent muscular contraction. A young person, aged 19, who had a moveable clot of blood in the posterior chamber, was observed to squint from the attempt to place a transparent portion of the medium opposite to the object looked at, and thereby to avoid the inconvenience produced by the presence

of the clot in different parts of the chamber. As soon as she ceased to look at an object, she ceased to squint.

A disturbance in the relation of the refracting media the author thinks is the only way of accounting for some cases of strabismus which are produced suddenly after a blow, or a jarring fall on the seat or on the feet. The first effect of displacement is double vision; and the squint, at first temporary, lasting only during attentive vision, is gradually made permanent by the repeated endeavour to escape from this fatiguing symptom.

The third form, viz. from partial paralysis of the retina, is more difficult of actual demonstration, though its presence may be inferred by induction rigorous enough for practical purposes. Amaurotic patients, when endeavouring to distinguish a light, are seen to turn the eye in different directions where they know the light does not exist; they present the various surfaces, as it were, feeling for it. Those in whom the paralysis is but partial contract a habit of subjecting to the influence of the rays the part that is most sensible.

The author believes that in no case of secondary optical strabismus will the texture of a muscle be found fibrous, and that in no case of primary mechanical muscular strabismus will such a fibrous state of the muscle be wanting. Where myotomy has been performed in cases of optical secondary strabismus, he believes that one of three things must have happened—either the case has not been watched long enough to ascertain the result, or a positive failure has followed, or the primary cause, whatever it may have been, has really been removed by the operation. The author adds a summary of the distinctive characters of the two kinds too concise to be materially abridged, but too long for our pages. The paper, which is to be continued in the next number of the journal, is well worthy of perusal.—*Gazette Médicale*.

CASES OF CLOSURE OF THE VAGINA IN INFANTS AFTER BIRTH.

By J. C. NOTT, M. D.

CASE I.—In the early part of 1837, I was requested to see the infant daughter of Mrs. P., of Mobile, aged 12 months. The mother and nurse both affirmed that the child was healthy and free from any deformity at birth, and for at least three or four months afterwards. They further stated that they had accidentally discovered, a few days before consulting me, that the vagina was closed, but were unable to say at what time this had

taken place, as there had never been any inflammation, discharge from the parts, or any circumstance to attract particular attention.

On examination, I found perfect adhesion of the labia, and closure of the vagina—the orifice of the urethra alone remaining open. The appearances were those of a congenital deformity, the parts being healthy, and the position of the os externum being marked by a superficial sulcus. The child was teething, and as I saw no good reason for immediate interference I advised that nothing should be done until this period was gone through. The parents with the child went to Scotland to spend the summer, and when they returned in the winter, I found, on examination, that the vagina had opened *spontaneously*—the parts were perfectly natural, and have remained so ever since.

CASE II.—In July last, Dr. M'Nally called on me, and asked me to see with him a child, about the same age, and under circumstances so similar in every respect, that I deem any details unimportant. I related the above facts to him, and we agreed to leave the case to nature for a few months.

We have recently examined this patient again, and find that a spontaneous opening has taken place as in the other case.

REMARKS.—These cases are not of frequent occurrence, are not to be found in our common works on surgery and diseases of children, and may embarrass the inexperienced practitioner. There can be no objection to the delay of an operation, and it is always prudent to avoid cutting if possible.—*American Journal of the Medical Sciences*.

HEMIPLEGIA FROM TYING THE COMMON CAROTID ARTERY.

A MAN was wounded, on the night of the 11th April, behind the right branch of the lower jaw. A large arterial jet of blood instantly flowed, which was in vain attempted to be staunched by means of compresses. Dr. Francis cut down on the wounded artery and applied a ligature to the vessel, which arrested the hemorrhage for three days. After this it returned with double intensity, and even the tourniquet failed to arrest it completely. On the 23d of April, Professor Sedillot was called to see him, and resolved to cut down on the common trunk of the carotid artery, and throw a ligature around it, as an aneurismal tumor had formed at the site of the wound, and the parts over which the tourniquet had been applied were in a gangrenous state. A ligature was with difficulty thrown around the vessel, the diffuse phlegmonous inflammation having confused the aspect of the parts. This ligature

arrested the hemorrhage, and the pulsation of the tumor disappeared. When the operation was performed the patient was in a state of extreme prostration, so that the other consequences of the ligature, other than what is stated, were not then observed. But when visited three hours afterwards, it was found that complete hemiplegia of the left side of the body and the right side of the face had taken place, and the intelligence of the patient was so far destroyed that he scarcely comprehended questions addressed to him. He died on the 2d of May.

The vessels were injected previous to opening the body, and when the skull-cap was removed and the brain examined, to ascertain, if possible, the cause of the hemiplegia, it was found that the arteries distributed to the right middle and anterior lobes of the brain were much less injected than those of the left side. These same lobes were also appreciably softer in consistence than those on the left side, but had apparently undergone no other change. No serous fluid was found in the ventricles, none on the surface of the brain. The hemiplegic symptoms, then, had apparently resulted from that side of the brain having been deprived of its due proportion of arterial blood. As the chief interest of this case depends on the hemiplegic symptom and the probable cause, it is unnecessary to detail the other morbid appearances.—*Gazette Médicale de Paris*; and *Edin. Med. and Surg. Journ.*

BIRMINGHAM SCHOOL OF MEDICINE.

We are requested to announce, that the arrangements for providing collegiately for the board, lodging, and tutelary care of the students of the Birmingham School of Medicine and Surgery, under the care of a Warden, are completed.

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE XXVII.

*On the invention and use of the forceps in
protracted and difficult labour.*

ON the 19th August, 1670, I saw, says Mauriceau, a little woman, æt. 38, who had been eight days in labour with her first child, the liquor amnii having escaped on the first, with very slight dilatation of the uterus. Having remained in this state to the fourth day, I was called to deliver my opinion upon the case to the midwife, whom I advised to have the patient bled, and in the event of the bleeding failing to produce any good effect, to give two drachms of infusion of senna to excite uterine contractions, which was done the following day; when the uterus dilated as much as was possible. Nevertheless, the head could not pass, in consequence of the great distortion of the pelvis, and I was again called three days after, but finding, from the narrowness of the passage, that it was impossible to guide the crotchet to the head with safety, I declared to all the assistants that the delivery could not be effected, of which they being fully persuaded, urged me to draw the child from the belly by the Cæsarean operation, which I would not undertake, knowing well that it is always very certainly mortal to the mother. But after I had left this woman without being able to afford her relief, there arrived unexpectedly an English physician, named Chamberlen, who was then at Paris, and who, from father to son, practised midwifery in London, where he has since acquired the highest

degree of reputation in this art. This physician, seeing the woman in the condition I have described, expressed his astonishment that I, whom he pronounced and affirmed to be the most dexterous accoucheur in Paris, could not deliver her, and promised that he would certainly do so in less than the half of a quarter of an hour, whatever difficulty he might encounter. He accordingly went to work, and laboured upwards of three hours without stopping to take his breath, and then being thoroughly exhausted, and seeing the poor woman almost dead, he was compelled to abandon the case, and avow that the delivery could not be effected, as I had declared. The woman died undelivered 24 hours after, and I found, on opening the body, which I did by performing the Cæsarean operation after death, that the whole uterus was torn and pierced in several places by the instruments which this physician had employed blindly, without the direction of the hand, which, being one-half larger than my hand, could not be introduced. Nevertheless, this physician had come to Paris six months before in the hope of making his fortune, having raised a report that he had a secret peculiarly applicable to labours of this kind, boasting that he could with it complete the most hopeless and desperate cases. He had even offered to communicate his pretended secret to M——, the first physician of the king, for 10,000 crowns. But the result of this unfortunate labour disgusted him so much with France, that he returned to England in a few days, seeing clearly that there were men in Paris far more skilful in the art of midwifery than he. But before setting off for London he paid me a visit to compliment me on my book, which I had published two years before, to inform me that he had never previously seen so difficult an operation as the delivery of this woman, and to praise me because I had refused to undertake it as inconsiderately as he had done. I received his congratulations as I ought, giving him to

understand that he was thoroughly deceived in believing that it was as easy to deliver women in Paris as he had found it in London, to which he returned the following day, carrying with him a copy of my book, a translation of which into English he published in 1672. Since this translation appeared, he has acquired so high a reputation in the art of midwifery in London, "*qu'il y a gagné plus de trente mille livres de rente, qu'il possède présentement, à ce que m'ont dit depuis peu de personnes de sa connoissance.*"

Dr. Hugh Chamberlen, in his preface to the translation which he published of Mauriceau's work in 1672, and which is entitled "*The Diseases of Women with Child and in Child-bed, as also the best means of Helping them in Natural and Unnatural Labours, with fit Remedies for the several Indispositions of New-born Babes,*" &c. gives the following account of his important secret, and explanation of the reason why it was not divulged, as he obviously felt ought to have been done. "In the 17th chapter of the second book, my author justifies the fastening hooks in the head of a child that comes right, and yet, because of some difficulty or disproportion, cannot pass; which I confess has been, and is yet, the practice of the most expert artists in midwifery, not only in England but throughout Europe, and has much caused the report, that where a man comes, one or both must necessarily die; and is the reason of forbearing to send till the child is dead, or the mother dying. But I can neither approve of that practice nor those delays, because my father, brothers, and myself (though none else in Europe as I know) have by God's blessing, and our industry, attained to, and long practised, a way to deliver women in this case, without any prejudice to them or their infants, though all others (being obliged, for want of such an expedient, to use the common way) do, and must endanger, if not destroy, one or both with hooks. By this manual operation a labour may be despatched (on the least difficulty) with fewer pains, and sooner, to the great advantage, and without danger, both of woman and child. If, therefore, the use of hooks by physicians and surgeons be condemned (without thereto necessitated by some monstrous birth), we can much less approve of a midwife's using them, as some here in England boast they do; which rash presumption, in France, would call them in question for their lives. In the fifteenth chapter of this book my author proposes the conveying sharp instruments into the womb, to extract the head, which is a dangerous operation, and may be much better done by our fore-mentioned art, as also the inconvenience and hazard of a child dying thereby prevented, which he supposes in

the twenty-seventh chapter of this second book. I will now take leave to offer an apology for not publishing the secret I mention we have to extract children without hooks where other artists use them, viz. there being my father and two brothers living that practice this art, I cannot esteem it my own to dispose of nor publish it without injury to them; and think I have not been unservicable to my own country, although I do but inform them that the fore-mentioned three persons of our family and myself can serve them, in these extremities, with greater safety than others."

The secret which the Chamberlens possessed was the midwifery forceps, which they had invented and perfected—it has undergone no essential improvement since; and the glory of the discovery both of the forceps and vectis, notwithstanding the sordid avarice with which they were so deeply tainted, and the utter disregard to the claims of humanity which they manifested by their mysterious conduct in concealing their instruments after the acquisition of the wealth which they so eagerly coveted, must in justice be awarded to them in all future ages. A variety of forceps had been invented long before the time of the Chamberlens, but they were unquestionably the first who discovered the true principle upon which the instrument can be employed with advantage—the separate introduction and subsequent locking of the blades. But except this short notice, contained in the preface to the translation of Mauriceau's work, from which nothing can be learned respecting the construction of the forceps, the method of applying it, and the cases of labour in which it could be used with advantage, no further account was ever given by them of their secret; and the Chamberlens, father and sons, and grandsons, Hugh, Peter, and Paul, had all died, and the whole family, I believe, had become extinct (about a century and a half had passed away) before it was known with absolute certainty what instrument it was they had invented. The extraordinary manner in which this became known in 1818 has been described by Mr. Carwardine, in a short paper published in the ninth volume of the *Medico-Chirurgical Transactions*, which I shall read to you.

"In depositing the obstetric instruments of the Chamberlens," says Mr. Carwardine, "among the archives of the *Medico-Chirurgical Society*, I beg leave to offer a few facts and observations which may serve to authenticate their genuineness and their originality. The estate of Woodham, Mortimer Hall, near Maldon in Essex, was purchased by Dr. Peter Chamberlen some time previous to 1683, and continued in his family till about 1715, when it was sold by Hope Chamberlen to Mr. William

Alexander, wine-merchant, who bequeathed it to the Wine-Coopers' Company. The principal entrance to the mansion is through a porch, the masonry of which, being carried up with the building, serves as closets to its respective stories. Two or three years ago, a lady with whom I am intimately acquainted, and from whom I had the particulars, discovered in the floor of the upper closet a hinge, and tracing the line she saw another, which led to the obvious conclusion of a door; this door she soon found means to open. There was a considerable space between the floor and the ceiling below, and this space contained divers empty boxes, &c. Among those was a curious chest or cabinet, in which was deposited a collection of old coins, trinkets, gloves, fans, spectacles, &c. with many letters from Dr. Chamberlen to different members of his family, and also these obstetric instruments. Being on terms of intimacy with the family resident at Woodham, Mortimer Hall, these instruments have been presented to me, and I have now the satisfaction of depositing them with your society for the gratification of public curiosity, and to secure to Chamberlen the meed of posthumous fame due to him for his most useful discovery. With respect to these instruments, I would briefly observe that they appear to me to contain *within themselves* the most direct and conclusive evidence of originality of invention; and that even the progress of this invention may be distinctly traced in its different stages as it passed through the mind of the inventor. First we have a simple vectis, with an open fenestrum (supposed to be of much more recent invention); then we have the idea of *uniting two* of these instruments by a joint, which makes each blade serve as a fulcrum to the other, instead of making a fulcrum of the soft parts of the mother, and which also unites a power of drawing the head forward. This idea is at first accomplished by a pivot, which, being riveted, makes the instrument totally incapable of application. Then he goes to work again, and having made a hitch in each vectis for the joint, he fixes a pivot in *one* only, which, projecting, is to be received into a corresponding hole in the other blade after they have been applied separately. It may be observed, that although there is a worm to the projecting part of the pivot, yet there is no corresponding female screw in the hole which is to receive it. Every practical accoucheur will know that it is not easy, or always possible, to lock the joint of the forceps with such accuracy as to bring this pivot and hole into apposite contact. This Chamberlen soon discovered, and next produced a more light and manageable instrument, which instead of uniting by a pivot, he passes a tape through the two holes and winds it round the joint, which

method combines sufficient accuracy of contact, security, and mobility. From the roughness of the workmanship, I am led to conclude that Chamberlen was his own artificer: a practice, I am told, not uncommon in those days, when mystery and empiricism were not regarded as contemptible even among the enlightened professors of science."

When secretary to the Medical and Surgical Society ten years ago, I obtained permission from the council to have models made of all these instruments described by Mr. Carwardine, the originals of which are still preserved. These models are now before you upon the table, and if you examine them you will come to the same conclusion as he did, that they contain within themselves the most direct and satisfactory evidence of originality of invention, and that even the progress of the invention may be distinctly traced in its different stages from the vectis to the forceps as it passed through the mind of the inventor.

The two figures which follow represent a front and side view of one of the levers or vectes found among the Chamberlen instruments. The other vectis in the collection has the extremity of the handle blunt.

Chamberlen's lever—the front and side views. The only difference between this and the other specimen found consists in the one being blunt at the extremity of the curved handle, while this terminates in a sharp point.

If you compare the two first figures which follow, and which represent the most perfect Chamberlen forceps, with the other two figures, which represent the straight forceps of Denman, now in common use, you will perceive that they are essentially the same instruments. The wooden handles and lock of Denman's forceps were invented by Smellie, and this is the only difference which exists, and it is not an important one,

between the Chamberlen forceps, and the short straight forceps of Smellie and Denman. The length and form of the blades, and the openings in them called fenestræ, are as nearly as possible the same, and undoubtedly had the same origin. It is evident from the form and construction of these forceps, and those of Chapman and Giffard, that an imperfect knowledge of the instrument employed by the Chamberlens had been obtained before 1733 by some means at present wholly unknown. I wish some evidence could be furnished to prove that this information was communicated by the authors of the discovery.

The accompanying cut is taken from a drawing of the most perfect of Chamberlen's instruments. No. 1 is the forceps locked: *a*, the blades; *b*, the handles; *c*, the hole in the joint, through which is passed the string to connect the blades.

No. 2, the front view of a single blade: *a*, the fenestra; *b*, the groove in the shank, forming the lock, by which the two blades, perfectly similar in form, are adapted to each other; *c*, the handle.

The following are the dimensions: extreme length, 11½ inches; length of blade, 7½ inches: of handle, 4½; greatest width between the blades, 3 inches and 3-8ths; width between the blades at the points, 3-4ths of an inch; greatest breadth of the blade, 1½ inch.

It has been stated in several of the historical accounts which have been published of the forceps, that about 16 years after the occurrence of the case at Paris related by Mauriceau, Dr. Hugh Chamberlen was compelled to take refuge in Holland in consequence of espousing the cause of James II. While in Holland he sold the lever to Roonhuysen as the secret which he possessed, but there is no evidence to prove, as Alphonse Le Roy asserts, that he parted with the forceps. The vectis was afterwards sold to two Dutch accoucheurs, Bekelman and Ruysch, who afterwards, according to Oslander, made a disgraceful trade with it. It would

1, Denman's forceps closed.
2, a single blade.

appear from his history of their proceedings that they not only frequently employed it for the sake of obtaining the sum which was usually paid to them for their assistance, but that they sold to others, over and over again, the same secret at an enormous price. Sometimes too they bargained for the half of what might be gained by the use of the instrument, and in the end it appears that they gave to every individual a new instrument as the true one, with the view, if any one should be inclined to betray the secret, the public might always remain in doubt which was the genuine instrument. None of the Dutch accoucheurs were so patriotic, or possessed so much humanity, as to disclose the secret of the Chamberlens. The immense gains, however, which the possessors of the secret made, rendered men of science most anxious to find out their secret. With this view Palfyn of Ghent made several journeys to Amsterdam and London for the purpose of finding out some clue to the discovery of the Chamberlens. After he had collected as much information at both these places as he was able, he had an instrument made which consisted of two steel blades like spoons, which were to be placed over the head of the child situated in the pelvis, by which with the assistance of two iron handles it might be drawn out. Palfyn went to Paris in 1723, fifty-one years after the translation of Mauriceau was published, and shewed this instrument to the members of the Royal Academy of Sciences as his own discovery. If you look at this representation of Palfyn's instrument in Mûlder's plates, you will see that he had not obtained accurate information respecting either the lever or forceps of the Chamberlens. It consists of two blades without a lock, and altogether very unlike the

Chamberlen forceps, and obviously useless in practice. Palfyn's instrument underwent several changes before it acquired that form which it possessed when it received the name of Duse's forceps, an account of which was first published by Butter in the *Edinburgh Medical Essays and Observations* in 1733.

"The forceps," says Butter, "for taking hold of a child's head when it is fallen so far down among the bones of the pelvis that it cannot be pushed back again into the uterus, to be extracted by the feet, and when it seems to make no advances to the birth by the throes of the mother, is scarce known in this country, though Mr. Chapman tells us it was long made use of by Dr. Chamberlen, who kept the form of it a secret, as Mr. Chapman also does. I believe, therefore, that a sight of such an instrument, which I had from M. Duse, who practises midwifery at Paris, and who believes it to be his own invention, would not be unacceptable to you, and the publication of a picture of it may be of use to some of your readers." This figure [exhibiting it] represents this instrument of Duse, but you see it is very widely different from the Chamberlen forceps. The handle and lock bear some resemblance to it, but the blades of Duse's forceps are merely two deeply concave steel plates, like spoons, without fenestræ. This was, I believe however, the nearest approach to perfection in the construction of the forceps which was made on the Continent before the representation of the English midwifery forceps was given by Giffard and Chapman in 1734 and 1735. The first edition of Chapman's *Treatise on the Improvement of Midwifery*, which contained a description, but no representation of the forceps, appeared in 1733, or earlier; and in 1734, Giffard's *Cases in Midwifery* were published, with this figure [exhibiting it] of what is usually called Giffard's extractor, which, you see, is the same instrument as that delineated by Chapman in the second edition of his *Treatise*, published in 1735. Giffard does not lay claim to the invention of the forceps, nor is there any account of the manner in which he came to the knowledge of it; there is no intimation by him that the instrument was kept secret, and he speaks of it as well known. Chapman says, "the secret mentioned by Dr. Chamberlen, by which his father, two brothers, and himself, saved such children as presented with the head, but could not be born by natural pains, was, as is generally believed, if not past all dispute, the use of the forceps, now well known to all the principal men of the profession, both in town and country." "As to forceps," he adds, "which I think no person has yet any more than barely mentioned, it is a noble instrument, to which many now living owe

their lives, as I can assert from my own knowledge and long successful practice." He then proceeds to describe the way in which it is to be used. "This instrument, though not pointed, must yet be used with caution. You are first to pass one part thereof above, gently introducing it, and guarding and directing the bow as far as you can with all the fingers of the left hand, the instrument lying in the hollow of the hand, being careful that no fold or part of the vagina get between the instrument and the head of the child, which would at once hinder any hold of the head (and consequently foil you in the attempt), and bruise the part that intervenes. But a little care will easily prevent this. One part thus passed over the head, and under the os pubis, the other is to be passed near the os sacrum, and thus a laceration will be avoided. When those are passed, they are then to be brought close together, and if you please the screw may be put through and fastened with the button, though there is no occasion for the loss of so much time, for without doing this the hand will prove sufficient to keep them together; and thus you may extract the head, by drawing gently down. It is much better, as I have just observed, that the two parts of the forceps should not be joined or fixed by a screw, the hand being sufficient, and that for these reasons. First, because when they are screwed together, though they should not happen to be exactly opposite to each other, yet they will turn so as to take fast hold of the infant's head, and readily extract it. Secondly, in case one of the parts should slip, it is then easily returned to its proper post, without being taken wholly away; whereas, when they are screwed together, and then slip off on one side (which I have often experienced, in spite of the greatest care I could use), the instrument is to be repassed and screwed as at first. They have oftentimes slipped, and when I expected the head of the child I have been deceived, and found the handle part come close, the instrument only in my hands, and the work all to do over again. I have always found the instrument far less apt to slip since I omitted fastening the parts together; and with more ease to the patient as well as myself, and in much less time than before, have found the head of the child fairly fixed in the instrument, that is, between the two parts or bows: so that, in a few seconds of a minute, I have had the child's head with the instrument, after which little or no difficulty remains. Thus I have delivered several women since my coming to town, some of whom you will find mentioned in the cases at the end of this treatise; and Mr. Gifford, in Case xiv. and elsewhere, frequently complains that his extractor slipped, which I am fully persuaded it would not have done if the parts had been

left unjoined, as I now use them. I do ingenuously confess that I came by this hint and improvement by mere accident, as, I believe, is frequently the case in discoveries of the greatest importance. For many years my forceps happened to be made of so soft a metal as to bend or give way, or suffer some alteration in their curve. They were made as usual with the screw fixed to one part or side of them. These I used for some years; but they often happening to slip off sideways (as before mentioned), my opinion of the instrument was so much lessened, that for many years after I used it but seldom, and even not once in the space of ten years, during which time, when the child could not be turned, I employed the fillet only. This I freely communicated to a very ingenious practitioner, now living in the country, who will, I doubt not, remember it upon reading this. At length I caused another pair to be made me, of better metal, and some other improvements, the screw part being contrived to take out, and not fixed as in the former. This screw I happened to lose in the clothes at the delivery of a woman who, with her child, is now living, and in health, in town; and being sent for to another presently after, and being, indeed, forced to make the trial, found that the instrument did its office much better without the screw, or the two parts being fixed. All I can say in praise of this noble instrument must necessarily fall short of what it justly demands. Those only who have used it to their own advantage, and the security of their offspring, can be truly sensible of its real worth."

Chapman was aware that the forceps could not be employed with advantage till the greater part of the head of the child had passed through the brim into the cavity of the pelvis. The forceps cannot be used, he says, "if the head does not lie very low, nor is their use to be otherwise attempted." He had clearly ascertained that it could not be used with safety if the head remained above the brim of the pelvis, and the uterus was imperfectly dilated. "I would of all things," he says, "advise the operator to be particularly cautious in his inquiry whether the infant in the womb be dead or not, if he chooses to employ the hook, or the child does not lie low enough for the use of the forceps, and the parts are so straightened that he cannot easily turn it; for there have been many deplorable instances of infants that have been drawn out this way as dead, whilst they have been really living." He admits, however, when it is past all dispute that the child is really dead, that then the delivery may with propriety be effected with the crotchet. From the history of the case of distortion of the pelvis related by *Mauriceau*, it is evident that though the

Chamberlens possessed the forceps in the most perfect form, they had not become acquainted with the cases to which it was applicable. But Chapman had discovered that in distortion the head did not descend sufficiently low to be taken hold of by the forceps, and that the only method of delivery with safety to the mother was by lessening the volume of the child's head."

"Though I have in some places of this *Treatise*," he observes, "condemned the use of the hook, and shewn that a child far advanced with its head is to be extracted with the forceps or fillet, yet I would not be thought to advance that it ought never to be employed: because there are some deformed subjects, as the two last mentioned, in whom the bones of the pelvis have so bad a structure, and the space between the protuberance frequently mentioned, and the os pubis, is so very small, as to render it altogether impossible for the head of a full-grown child to be naturally brought away. In these subjects the head cannot fall into the vagina low enough to be taken hold of by the forceps or fillet, nor can it be turned without the greatest difficulty: and even when it is turned, it will certainly stick at the head. In this case it cannot be drawn away but by the hook, which will break into its texture, alter the form of it, and so render it fit to pass through that passage, which it could never do if it were whole." It thus plainly appears that we are not only indebted to Chapman for the first description of the midwifery forceps, but for the discovery of the principles which ought invariably to guide us in its employment.

The following figures represent the forceps of Chapman and Giffard.

SOME PRACTICAL REMARKS
ON THE
EMPLOYMENT OF ARSENIC IN
THE TREATMENT OF THE
DISEASES OF THE SKIN.

BY JOHN E. ERICHSEN.

[Concluded from p. 242.]

Among the exanthemata there appears to be but one affection that can ever require the exhibition of arsenic; this is *urticaria tuberosa*, a rare disease, and one that I have never had an opportunity of observing. Cazenave, however, relates a case as occurring under Biett, in which it became necessary to have recourse to Fowler's solution.

The only papular disease that ever necessitates the administration of arsenic is *lichen* in its most chronic and rebellious forms. In very obstinate cases of this affection, especially in those varieties of *lichen circumscriptus* that are confined to the face or to the margin of the anus, and the genital organs, in which the skin becomes red, excoriated, chapped, and furfuraceous; or in the chronic confluent form of the eruption, when the whole of the body is covered by papulæ, capped with thin flimsy scales, having a close resemblance to pityriasis, the irritation and consequent insomnia being most distressing, it may become necessary to exhibit one or other of the preparations of this mineral. Biett was in the habit of ordering the "Asiatic Pills," one a day for a month or more. Rayer recommends either Pearson's or Fowler's solutions, due attention being paid to those circumstances that have already been spoken of as contra-indicating their employment. I would give the preference to Fowler's solution, as it is a milder preparation than the arsenious acid. It should be borne in mind, however, that these remedies are only admissible in those cases of *lichen* in which all other means of cure have failed, and in which the patients are worn out by the irritation and restlessness that are the usual consequences of this disease in its more severe and intractable forms. In proof of the value of Fowler's solution in very obstinate and chronic forms of *lichen*, I may mention the case of a girl named *Mary Ann Dockett*, nine years of age,

with delicate complexion, and dark hair and eyes, who lately came under my care for confluent lichen of the whole of the body, with the exception of the face, part of the chest, the palms of the hands, and soles of the feet. The whole of the rest of the surface was studded with an immense multitude of papulæ, somewhat resembling, but more closely set than, those which occur in the cutis anserina: these papulæ, which were particularly distinct about the outer sides of the thighs, arms, and back, were covered with exceedingly minute, flimsy, whitish scabs, giving the skin a powdery appearance. The head was very scurfy, and the hair crisp and dry. At times there was considerable irritation in the skin, which became reddened and cracked, more particularly about the bends of the arms and knees. The mother states that the child has been affected from birth, and that the disease is hereditary on the father's side. As various remedial measures had been resorted to, but without success, and as the child's health appeared to have suffered from the effects of the disease, I determined to have recourse to the solution of the arsenite of potassa. She was accordingly ordered to take one minim of the solution twice a day, to have the whole of the affected parts well anointed every night with a mixture of sweet oil and spermaceti ointment, and to take a bran bath in the morning. After having continued the treatment very little more than a month, during which time she was only obliged to discontinue the arsenic, the dose of which had not been increased, once, and that for a space of four days, the skin had recovered its natural smoothness, which has ever since been preserved by the use of the unction and warm bath.

The only disease amongst the vesiculæ that can ever necessitate the employment of arsenic is *chronic eczema*. This is more particularly the case when this affection, as has already been stated, has assumed a furfuraceous or scaly condition, closely resembling some forms of psoriasis, or pityriasis, and indeed in some instances, as Biett has shown, actually passing into these diseases; the scales becoming dry, laminated, and of a whitish, greyish, or yellowish-grey colour; the subjacent skin being red, thickened,

cracked, and inflamed; the vesicular element, however, reappearing in the progress towards a cure. However obstinate this form of the disease may usually be, it becomes particularly intractable when affecting certain regions of the body, as the scrotum, labia, and inside of the thighs, and will, when of old standing in these situations, seldom yield to any remedy but arsenic. The following is a case in point:—

Mr. W. B. æt. 49, of relaxed debilitated habit of body, applied to me, in October last, for a disease of the scrotum, thighs, and breast, under which he had been labouring between four and five years. He ascribed his complaint to his having drunk some porter when over-heated, soon after which act of imprudence he experienced considerable irritation about the scrotum and thighs, on which parts a vesicular eruption made its appearance: this was followed by a scaly condition of the parts, and the affection, after a time, spread to other parts of the body, as the arms and chest. He has been subjected to a variety of treatment, and has been salivated twice, but without deriving any benefit. When he applied to me, the scrotum and inner aspect of the thighs were covered by a number of thin, flimsy, yellowish-grey scabs, from under and between which an occasional exudation of a serous fluid took place; the subjacent skin was red, inflamed, and fissured, and there were several patches of a similar character upon the chest, occupying a space of about the size of the hand, as well as one on the right arm. The itching and tingling in the affected parts were severe; so much so that it was with difficulty that he could keep his hands from tearing them. When I first saw him his mouth was sore from the effects of some mercurial that had been ordered by the physician who last attended him, and by whom he was sent to me. He was, therefore, in the first instance, merely directed to take some aperient medicines, and to make use of soothing applications to the affected parts. On the 4th November he was put upon a course of Fowler's solution, beginning with two and a half minims twice a day, and increasing the quantity up to six minims three times a day: this was continued, with two intermissions on account of constitutional disturbance, up to nearly

the end of December, when the disease was entirely cured. The external applications that were had recourse to were, in the first instance, the ointment of the white precipitate, which was, as the disease became more passive in its characters, changed for that of the biniodide of mercury, diluted with four parts of spermaceti ointment.

Useful as the solution of the arsenite of potassa unquestionably is in cases similar to the preceding one, it is equally serviceable in dry chronic eczema affecting other parts of the body, as the following instance will illustrate.

Eliza Penny, æt. 16, of a lymphaticobilious temperament, came under my care on the 17th November, 1842, for a disease of both arms under which she had laboured from the very earliest infancy (from the age of three months). The affection in question was clearly eczematous. The diseased integument appeared thicker and rougher than natural, was covered with flimsy exfoliations of the epidermis, was exceedingly irritable, itching and tingling to an intense degree when the patient got warm, and was much fissured about the bends of the elbows and wrists. There was every now and then an exacerbation of the disease with a distinct eruption of vesicles. The patient complained much of languor and lassitude, was pale, or rather sallow in complexion, and menstruated somewhat irregularly. She was ordered the diluted mineral acids internally, with the oxide of zinc ointment to the affected parts, and the pil. aloes cum myrrhâ, to regulate the bowels and menstrual functions. Under this plan of treatment the general health improved somewhat, and the irritability of the affected skin was subdued. She was then, on the 2d January, ordered to begin the solution of the arsenite of potassa in two-minim doses; these were gradually increased to five, and subsequently to seven and a half minims, three times a day: this she continued for a space of two months and a half, until the middle of March, without being obliged to intermit its use for a single day, at the expiration of which period the arms had assumed a healthy appearance, the skin being smooth, soft, and supple, perfectly free from scales, and without any harshness; it was, however, owing

probably to the very long time it had been diseased, of a yellowish or tawny colour, darker than that of the rest of the body. The only external applications used were, in the earlier stages, the ointment of the oxide of zinc, with occasional fomentations during the exacerbations of the disease; these were followed by the ointment of the white precipitate, and subsequently by a lotion of the sulphuret of potassium, in the proportions of a dram of the salt to a pint of water. The local disease was not only cured, but the general health very decidedly improved by the administration of the arsenic; the patient having gained flesh and strength, acquired a good colour, and declared herself to be in better health than she had ever enjoyed.

It is but seldom that we meet with cases of the pustular diseases that require the administration of arsenic. Bielt and Rayer, however, both state that they have occasionally found it necessary to have recourse to this remedy in some very chronic and rebellious forms of *impetigo*. Gibert relates two cases of *impetigo* of the face which had existed from infancy, and which Bielt cured by means of Pearson's solution, after many other plans of treatment had been employed without success. These cases are nevertheless very rare, but when they do occur it will be requisite to attend to those different circumstances that have already been mentioned as indicating, or contra-indicating, the exhibition of this metal.

Useful, however, as arsenic may be in many diseases of the skin, it is in the treatment of the squamous affections, more particularly of long-standing cases of *lepra* and of inveterate *psoriasis*, that it is incontestibly of the greatest service. For it is by no means rare to meet with cases of these diseases, which obstinately resisting, perhaps for years, milder methods of treatment, will in the course of a few weeks yield to the judicious employment of the preparations of this metal, the utility of which in this class of affections is so fully established by most dermatologists that it is almost needless to insist upon it. It was, indeed, the success that attended the employment of arsenic in the squamous diseases that first led to its introduction into practice as a most

valuable remedy in other affections of the skin. But, notwithstanding its utility in this class of diseases (the squamous), it is not admissible in every stage of their progress, nor indeed is it required in the great majority of these cases; far from it: it is only in very extensive and obstinately rebellious forms of these complaints, or when the patient is suffering some very positive inconvenience from the disease, that we should be justified in administering it, and then only in the absence of those circumstances that have already been pointed out as contra-indicating the administration of arsenic in other affections.

With regard to the stage of *lepra* and *psoriasis* in which the preparations of this metal may be administered, it should be laid down as a rule that they should not be given until the disease had assumed a decidedly chronic, inactive character. So long, indeed, as there is any inflammatory redness, heat, or irritation about the patches, they should never, under any circumstances, be employed, as the stimulus of the arsenic would almost infallibly augment the severity of the disease; besides, during the earlier periods of the complaint, we should probably be able to effect a cure by other and less heroic measures. It is only, then, in very long standing cases of an extensive and indolent squamous disease, in which all other means of treatment that are likely to benefit have been employed without success, that these remedies should be given. And even then, as Rayer justly remarks, as these diseases frequently exert no evident ill effects on the constitution, the inconvenience they occasion being but very trifling, it will be advisable to confine the treatment to a palliative one, unless the patient positively insist on some active measures being adopted, when we should not hesitate to have recourse to the employment of the arsenicals, due attention being paid to the temperament of the individual, and to the state of his digestive organs.

In the majority of cases of *lepra* or *psoriasis*, Fowler's solution will, I think, be found the most useful preparation of arsenic that we can employ. The liquor of the hydriodate of arsenic and mercury has been very successfully exhibited in cases of this description, as has also the

iodide of arsenic, either alone, or, if the disease be of a syphilitic nature, in combination with the biniodide of mercury and extract of conium. Instances illustrative of the value of these preparations have been adduced in a former part of this paper. The "Asiatic pills" were strongly recommended, and, according to Cazenave and Schedel, employed by Biett with advantage, in cases of psoriasis inveterata: they are, however, open to the objection of being less manageable than the other preparations of arsenic.

When these remedies are about to exercise a beneficial influence in cases of lepra and psoriasis, it will be observed that an increased action appears to take place in the diseased cutis, which becomes red, inflamed, and irritable; the scaly patches then appear to heal up, either from the centre or the circumference, according to the nature of the affection, whether it be lepra or psoriasis, and eventually fall off, leaving the subjacent skin red, smooth, shining, and covered by thin epidermic exfoliations, which may usually be readily cleared off by stimulating topical applications, such as the ointments of tar, or of the nitrate or the biniodide of mercury; after which nothing but a red stain will be left in the site of the squamous patch. And this will soon disappear if the remedies be persevered in, which they should always be, until this blotch is entirely and effectually removed; for, until this be accomplished, the disease will be very liable to return: indeed, it is from a want of due attention to this very important circumstance, that the arsenical preparations have been so often accused of effecting merely temporary cures. We must not be content with removing the scales merely, which are secondary phenomena, but we must get rid of the primary lesion, that peculiar inflammatory or congested state of the blood-

cutis, which, by giving
red and morbid secre-
tions, is the proximate
cause.

In cases of squamous
we have seen the pre-
: employed with
specially mention one,
for the very short
hereditary affection
yielding yielded to
Fowler's solution.

Sarah Partons, ætat. 20, of lymphatico-sanguine temperament, being stout, rather pale, with gray eyes and light brown hair, came under my care on the 12th January, for psoriasis of the legs, arms, knees, and elbows, of thirteen years' standing. Her father and brother (who is now under my care) labour under the same disease. There are a number of patches of psoriasis, varying from the size of a sixpence to that of a crown piece, about both legs and arms, and a few on the back. Immediately below the left knee there is one as large as the palm of the hand, and the points of both elbows, but more particularly the left one, are covered by thick scaly incrustations, extending some way down the posterior aspect of the fore-arm. The diseased patches were in a very indolent condition, there being no inflamed areola about them, and being unattended by any tingling or itching. The general health was good, and there were no dyspeptic symptoms of any kind. As the disease was of such long standing it had been subjected to a great variety of treatment, and she had been a patient at two of the metropolitan hospitals, at one for a period of eight months, without receiving any benefit. I therefore, as she was very anxious for a cure, determined to try at once the effect of arsenic, and accordingly ordered her two and a half minims of the solution of the arsenite of potassa twice a day; the biniodide of mercury ointment diluted with three parts of ung. cetacei, to be rubbed into the diseased patches night and morning. The quantity of the solution of the arsenite of potassa was gradually increased until the 27th, when she was taking seven and a half minims three times a day. By this time the diseased patches on the arms, and some of those on the legs, had been cleared of their scales; the affected skin was, however, redder than natural, and rapidly covered itself with scales of epidermis if the use of the ointment was interrupted. On the 28th some constitutional derangement, as headache, lassitude, pain in the eyes, and thirst, came on: the solution was accordingly discontinued. On the 4th February it was resumed in doses of five minims three times a day, which quantity was continued without any disturbance, either local or constitutional, until the 10th March, when, as the disease appeared to be entirely

cured, with the exception of a red stain as it were, of the skin in the site of the affected patches, the dose of the solution was diminished to three minims, which quantity was continued, in order to prevent a relapse, until the end of the month. The ointment of the biniodide of mercury had been persevered in during the whole of this time, its strength having been increased to equal parts of the ointment of the Pharmacopœia and of spermaceti cerate.

It may, then, be concluded, from what has been stated in the preceding pages, that the administration of such powerfully stimulating tonics as the preparations of arsenic should be guided by the same rules that govern the exhibition of this class of remedies generally. We should avoid using them, not only in certain kinds of diseases, but in any affection so long as there is any inflammatory action of an active nature going on about it; in persons of a plethoric habit of body, or of a sanguine or sanguineo-nervous temperament; and more particularly in those in whom there exists any irritation about the gastric mucous membrane, or any other inflammatory disease; and only administer them when the cutaneous affection occurs in an individual of a relaxed, debilitated, or lymphatic habit of body, when it has fallen into an indolent, passive state; and, more particularly, if it be a squamous disease, or if it have assumed a furfuraceous aspect, and can bear, without being permanently irritated, the application of a mild topical stimulant. If the administration of arsenic be regulated with a due regard to these circumstances, the doses being slowly and gradually increased, there is no reason why its exhibition should be attended with worse consequences than that of antimony, mercury, strychnia, or of any other very active remedy which we are in the daily habit of prescribing without any fear as to the effects that it may produce upon the system. There can be no question, however, that very injurious effects have resulted from the injudicious administration of the preparations of arsenic in too large doses: but the consequences of the abuse of any medicine are not fair arguments against its careful and guarded administration; and I feel convinced that arsenic may be exhibited with as much safety as any other powerful tonic in the Pharmacopœia,

provided due discrimination be shown in selecting the cases to which it is to be given. And it is by regarding the preparations of this metal in the light of *specifics* to be resorted to indiscriminately in the treatment of every obstinate and rebellious affection of the skin, without attention to the nature, stage, and complications of the disease, or to the habit of body and temperament of the individual in whom it occurs, that much mischief has resulted from, and opprobrium been cast upon a very valuable remedy.

Rickets.—Pathology and treatment of the affection.—Connection with enlargement of the liver and indigestion.—Its affinity to scrofula.—Scrofula.—Its pathology and treatment.—Gastrodynia.—Sometimes cured by a dietetical remedy.—Chronic hydrocephalus.—A CEREBRAL MURMUR symptomatic of its first stage.

CASE I. May 27, 1839.—Wm. Kates, aged 3 years and 2 months: was born healthy and stout, and continued to be so until he was three months old, when his teeth began to appear, and he had an attack of inflammation of the lungs. About, or shortly after that time, he was transferred from his mother to her sister, to be brought up by feeding. The child's health then became much impaired, and he has been always sickly and weak since. His present condition is as follows:—skin anæmatus and pale; flesh scanty and soft; legs and thighs bowed and emaciated, and body altogether approximating to a state of marasmus; can make no effort at standing or walking, and creeps but feebly; spine curved laterally; left side of thorax enlarged and projecting laterally and posteriorly; clavicles distorted; head has always appeared larger than ordinary, and at present there is a soft fluctuating tumor situated on the left parietal bone. His mother states that previous to the appearance of this tumor the sutures of the skull were very open; that he had a fall a few days ago from a bench high, on which she pitched upon his forehead the tumor appeared, appetite, and fall, but regular, expressed rather

℞ Hydrarg. c. Cretâ, gr. iij. ; Pulv. Rhæi, gr. iv. ; Cinnam. gr. j. ft. pulvis. Mitte vj. Sumat j. alterna nocte.
 ℞ Sp. Rosmar. ℥ss. ; Aq. Font. ℥vss. M. ft. Lot. tumore constanter applicet.

29th.—Tumor considerably decreased ; no perceptible change otherwise.

Continuentur lotio et pulveres, et hirudo tempore iterum applicetur.

June 1st.—Tumor of head almost disappeared, and some other little improvement.

Continue the lotion and the powders, and let the child have a warm salt water bath every other night at bed-time, and let him be well rubbed with a dry cloth, both on the body and limbs, for ten minutes after coming out of the bath.

5th.—The tumor on the head has entirely disappeared, and the parietal bone on which it was situated, which was fully a line depressed below the others, has become elevated to its proper position. Head much hotter than natural ; eyes dry and glassy-looking ; pupils rather dilated ; is fretful when awake, and frowns frequently in sleep, but does not start or grind the teeth ; tongue deficient in moisture, but not furred ; pulse rapid, and rather unresisting ; alvine excretions light-coloured ; is very thirsty ; hands hot. On applying the ear to the anterior fontanelle, or to the parietal bones, a murmur accompanying the cerebral circulation is very audible*.

Continue the powders, one every night, and the cold lotion to the head, and the warm bath without the salt ; let the child's diet be chiefly beef-tea, arrow-root, and milk and water.

July 1st.—Little or no alteration in any respect since last report. Head still much hotter than natural ; anterior fontanelle agitated, and cerebral murmur very loud over the entire of the head, with the exception of the os frontis ; eyes still dry and glassy-looking ; no strabismus, but frequent frowning. His mother states that the child frequently complains of pain over the left ear. Otherwise as before.

Let the head be closely shaved, and kept constantly wet with the cold lotion, and let two small leeches be immediately applied to seat of pain over left ear.

℞ Hydrarg. c. Creta, Pulv. Jalapæ, aa. gr. iij. ; Pulv. Ipecacuanhæ, gr. j. ; ft. pulvis mitte vi. ; Sumat j. nocte maneat. Continue the same diet.

5th.—No obvious change since last report.

Continue the cold lotion, powders, and diet, and apply two leeches again to the left parietal bone over the ear.

9th.—The leeches bled well ; the powders have been taken regularly, and the bowels have been moved thrice a day. The mother states that the child is becoming cheerful and better tempered, and more disposed to chat. Head still hot, and frequent perspiration from it and from the face during sleep ; cerebral murmur very audible even over the occipital bone ; frequent leering, but no strabismus ; abdomen hot, but arms and legs rather below the natural temperature ; appetite rather inordinate, and sleeps pretty well ; excretion of urine less frequent ; pulse frequent and resisting.

Continue the same treatment.

16th.—Has administered the treatment as prescribed faithfully. The condition of the child in all respects is much improved since last visit. He has put on flesh, and his limbs are becoming plump and firm. There is not now any frowning or leering, and the eyes are acquiring an expression of softness and animation. He has lost much of his fretfulness, and is now daily becoming more mild and more easily amused. The head is still hotter than natural, and the cerebral murmur is audible, but less intense. Renal secretion less, and appetite not so voracious. Bowels stated to be more regular, and their excretions of a more healthy character. Respiration and action of heart not disturbed.

Being struck to-day by the undiminished and still very protuberant state of the abdomen, after the use for some considerable time of aperient medicines, the thought occurred to us to examine it by percussion and pressure, when we found the liver enormously enlarged, the right lobe almost in contact with the crest of the ilium, and the left overlapping the stomach, and easily felt between two and three inches below the ensiform cartilage. The ends of the lower ribs, both on the right and left side, were considerably everted. Continue the same plan of treatment, and let us see the child again in the course of a week.

September 23d.—Had not seen the child now for more than two months. Little, if any, discernible change in its condition since last report ; but on the whole, perhaps, there is some improvement. The countenance looks better, and the child appears to have gained some more flesh ; liver somewhat reduced in size, but still much larger than natural, and very easily felt by pressure of the hand on the right side of the abdomen ; the child is not yet able to maintain the erect position, but it creeps with much more activity ; all other symptoms as before.

℞ Hydrarg. c. Cretâ, gr. ij. ; Hydrarg. Chlorid. gr. ss. ; Pulv. Rhæi, gr. iij. ; Pulv. Cinnamomi, gr. j. Ft. pulvis, mitte viij. sumat j. alterna nocte.
 ℞ Potassæ Bisulph. ℥ij. ; Sodæ Bicarb.

* Dr. Macleod, and Mr. Johnson (of Med.-Chir. Review), auscultated the head of this patient, and said they heard the murmur distinctly.

℞j.; Aquæ Menth. Pip. ʒix. Solve terendo, et adde Tinct. Rhei, Tinct. Sennæ, aa. ʒiss.; Syrup Aurantii, ʒij. Ft. mistura cujus capiat cochlearia parva tria omni mane. To have solid animal food at least once a day, and also a little beef-tea, with diluents of arrow-root or sago occasionally; to be warmly clothed, and to be as much in the open air as possible.

October 8th.—Has used the powders, mixture, and diet, and treatment otherwise, in all particulars regularly since last visit. Condition of child in all respects remarkably improved. His mother states that he sleeps well; that his appetite is not half what it was; that his disposition is quite changed, as he has lost all his peevishness; no frowning or leering, and countenance becoming full and animated; has gained considerable strength both of body and limbs, and can make some effort at standing; abdomen less protuberant, and liver further diminished in size, but still projects between two and three inches below the ribs on the right side; the ribs both on the right and left side are much less everted, and the shape of the thorax is altogether more normal; the cerebral murmur is still audible at all points of the cranium, but the forehead, and the left hemisphere of the cranium, on the parietal bone of which the tumor was situated, appears rather larger than the right. Continue the same treatment in medicine, diet, and exercise.

This patient now ceased to be under our care, and we entirely lost sight of the case; but we have every reason to suppose the little fellow continued to recover, or he would have visited us again.

CASE II. Sept. 11, 1839.—Eliz. Williams, aged two years and a half, of fair hair and fair complexion, eyes light blue, skin and subcutaneous tissue fine and soft, and the economy generally discovering a tendency to the strumous diathesis, was a very healthy child until after vaccination, which operation was performed upon her when she was about six months old, at which time, or immediately after, she commenced to cut her teeth, and a papular eruption made its appearance all over the body; and at the same time, also, the child's bowels and general health were much disordered, the alvine excretions being frequent, and showing some appearances of blood. The child has been in bad health, better or worse, ever since. Present condition as follows. Much fretfulness and irritability; sleep light and easily disturbed; countenance pale and dejected; irides decolourised; surface generally pale and chill; no emaciation, but flesh soft and flabby; no morbid curvature of the spine or of the bones of the chest, but the right leg is

very weak and bent inwards at the knee; liver considerably enlarged; it can be felt in the right hypochondrium, between two and three inches below the ribs, but it is not perceptible in the epigastrium; renal secretion stated to be natural in quantity and appearance; pulse and respiration undisturbed; no thirst, but appetite voracious. The head appears rather large, and the anterior fontanelle is still open, and on applying the ear to it or to either of the parietal bones a faint cerebral murmur is audible.

℞ Hydrarg. c. Cretæ, gr. iij.; Pulv. Jalapæ, gr. iij.; Pulv. Cinnamomi, c. gr. ij. Ft. pulvis, mitte vj. sumat j. alterna nocte.

℞ Infusi Sennæ, ʒvj.; Potassæ Bicarb. ʒss.; Mannæ Opt. ʒiss.; Tinct. Cinnamomi c. ʒj.; Aquæ Carui, ʒj. M. fiat mistura cujus capiat cochlearia parva tria omni mane. Let the child's diet be moderate in quantity, but let her have solid animal food in fair quantity once a day at least, and let her be much in the open air.

22d.—Has used the treatment prescribed regularly. Two excretions have taken place from the bowels daily of a more healthy character. The condition of the child is something improved; it is less fretful, and is more animated, and its appetite is not so voracious; little if any perceptible alteration in the size of the liver; the cheeks are still pale, but the colour appears returning to the irides; cerebral murmur and other symptomatic phenomena as before. The same treatment in all respects to be continued.

October 8th.—Has used the remedies prescribed regularly since last report; child's general condition and health altogether much improved; she is becoming lively and good-tempered, and sleeps well; countenance less exsanguineous and drooping; irides deepening in colour; appetite not voracious, but moderate; alvine excretions more regular and of a more healthy character; flesh becoming firm, and the cutaneous circulation generally more active; cerebral murmur audible now only at the anterior fontanelle, and here but faintly; abdomen much reduced in size, and softer; liver lessened considerably, but still projects below the margin of the chest.

Continue the mixture, powders, and diet, as prescribed, and let the child have a warm bath twice a week.

We saw this patient once again after some little time, when her health was all but completely restored. The countenance had acquired colour and animation, and she had become plump and active; she slept soundly.

and the alvine and urinary excretions were healthy; circulation and respiration the same; the liver was further reduced in size, but still to be felt under the right hypochondrium, but not at the pit of the stomach; the cerebral murmur had ceased to be audible on auscultation of the cranium at any point.

CASE III. Aug. 17, 1838.—Wm. Rogers, æt. 19 months, of light hair, light complexion, and blue eyes; was strong and healthy till he was eight months old, when he had an attack of illness of six weeks' duration, which his medical attendant pronounced to be inflammation of the lungs. This attack consisted chiefly in feverishness with cough and much disorder of the bowels. The mother states that the alvine excretions towards the latter part of the child's illness, were unhealthy and offensive, and contained substances like pieces of flesh. He appeared to have recovered from this attack pretty well, but about a month afterwards the head was first observed to be enlarged, and it has gradually increased in size since. Present condition as follows: general health not much disturbed, but face and surface generally anæmatus and pale; no emaciation, but flesh soft; sleep unquiet; bowels generally relaxed, but their excretions and also the excretion of urine stated to be natural in character; is still at the breast, but will eat any solid food that is presented to him; appetite rather inordinate; pulse 126, and regular; head large, circumference 22 inches and a half from each meatus auditorius, over the vertex 14 inches and a quarter; no dilatation of the pupils, but considerable strabismus, and the eyes remain half open and roll a great deal during sleep; anterior fontanelle large, and of a crucial shape where the cerebral movements are perceptible to the touch, and the *cerebral murmur* very audible on application of the ear. Has not had small-pox, measles, or any other of the eruptive fevers; was successfully vaccinated.

CASE IV. Oct. 16, 1836.—Mrs. A.'s infant, æt. 14 months, a pretty strong and large boy for his age, has been dull and listless for the last three or four days, and has rested badly the last two nights: at present he is unusually inanimate; the skin is harsh and increased in temperature; the bowels are irregular and their excretions fluid and of a light clay-colour, without the slightest tinge of bile: the head appears rather above what is ordinary in size, and the anterior fontanelle is open, and on applying the ear to this part a *cerebral murmur* is heard very distinctly; it is also audible, but less clearly, over the parietal bones; abdomen protuberant and somewhat resisting, but no enlargement of the liver can be detected; flesh rather soft; pulse frequent. For this patient

we prescribed a powder of hepatic alterative properties, which was taken every night, and occasionally every other night, at bed-time, with a dose of a mildly aperient mixture once or twice during the day; pretty full diet with solid animal food in fair quantity at least once a day; warm clothing and exercise in the open air at all times when the weather will permit of it. This child in a short time became quite stout and well.

REMARKS.—These four cases now described present us with examples of profound chronic digestive derangement and disease in children, similar, we conceive, in their origins, causes, and natures, but in different periods of progress, and different states of development. The first case, that of the boy Kates, which will form the subject chiefly of the following observations, is manifestly a case of tabes and rickets; the cause of the tabes being, in this instance, not in the glands of the mesentery, but in a glandular structure of far greater magnitude and importance, namely, the liver. To an examination less accurate with respect to the state of the abdominal viscera than that which was given to this case, by pressure and percussion, when, as we have seen, it had been some time under treatment, the diagnosis could scarcely have pronounced the affection other than tabes mesenterica. All the symptoms which are usually considered as peculiar to, and enunciative of, that scrofulous malady were present. There was the large protuberant abdomen, with the general and severe emaciation in contrast; the voracious appetite; the derangement of digestion, and disorder of the functions of the intestinal canal; the irregular hectic feverishness, and the diminished temperature of the extremities, with other minor symptoms. The white alvine excretions, which we find mentioned by almost all authors upon mesenteric tabes, as a pathognomonic sign of that affection, were not present. We entertain some doubts, however, on the perfect exemption from error of this diagnostic doctrine, and could give, we think, sufficient reasons for so doing. At present we will only observe, that we have seen white earthy excretions, not unlike the ashes of wood wetted, passed from the bowels, for months, by adults labouring under jaundice and organic disease of the liver. The fact, however, which deserves our first consideration, and which

makes the case now under comment more particularly interesting in a pathological and practical point of view, is the immense enlargement of the liver that was present in this infantile patient. No one, we believe, however recent and imperfect his knowledge may happen to be of any disease he may be called upon to treat, but forms some notion to himself of its cause and original idea, and prescribes his remedies accordingly. The more correct, too, are his thoughts on the etiological points of the case, the more likely, it is certain, are his remedial measures of being beneficial and successful.

The question, then, of most import and utility involved in the pathology of this case, and one, undoubtedly, which it is difficult to determine, is, what place, in an analysis of its constituent phenomena, should be assigned to the hepatic enlargement; whether should it be viewed as cause, or as consequence, or as a concomitant morbid condition? Sydenham, we find, has mentioned the enlarged state of the abdominal viscera (without having particularised the liver) which is present in children affected with rickets, and he appears to have considered both the affection of rickets and the visceral disease as consequences of intermittent fever—a sort of metastatic and critical deposition of the febrile matter. “Children sometimes become hectic after both *continued* and *intermittent* autumnal fevers. The abdomen in this case swells and grows hard, a cough also and other consumptive symptoms frequently arise, which manifestly resemble the rickets.” “It is worth observing, that when children have been long affected with autumnal intermittents, there are no hopes of vanquishing the disease till the abdomen (especially that part of it near the spleen) swells and grows hard; the distemper abating in the same degree as this symptom manifests itself. Nor can we, perhaps, more certainly foretell that the intermittent will go off in a short time, than by carefully attending to the swelling of the *abdomen* in children, and to that of the legs, which sometimes happens, in grown persons.” “The swelling of the abdomen which happens in children after intermittents, in those years wherein the constitution of the air has a tendency to produce autumnal intermittents epidemically, appears to the

touch as if the viscera contained matter hardened to a scirrhus; whereas, that which comes in other years yields to the touch, as if the hypochondria were only distended by wind. Hence it is worth notice, that the true rickets rarely happen except in those years wherein autumnal intermittents prevail.”—*Swan's transl. of Sydenham*, pp. 64, 65.

Baron Van Swieten, too, in his admirable Commentaries upon Boerhaave's Aphorisms, has not omitted to notice the increased bulk of the liver that accompanies the condition of rickets; but the particular part which it acts in the pathology of the disease he does not distinctly point out; he only assigns to it the place of a “concurrent cause,” as he terms it, of the protuberant abdomen. “I have often, (observes Van Swieten), had children brought to me to be cured, supposed by their mothers to have been troubled with great liver, when they manifestly had the rickets.” We shall hereafter see that in this disorder the liver is found of a vast size, though no other disorder can be discerned in this viscus after death. Glisson, upon examining the dead bodies of rickety children, thus testifies: “the liver, in all I have dissected, is greater than it should be; but otherwise is not of a bad colour, nor greatly indurated, or in other respects contaminated by any other remarkable vice.” He excepts some dead bodies in which other diseases had been complicated with the rickets before death, as he remembered to have observed in a dropsical and extremely tabid patient. From hence the reason appears why the rickets has, in some places, been distinguished by the name of *great liver*; he found no fault in the magnitude, colour, or substance of the spleen; yet he denies not that it might happen otherwise from a complication of rickets with other diseases.”—*Van Swieten's Commentaries*, vol. 17, pp. 339 and 367.

Our experience, we acknowledge, does not enable us to say to what extent enlargement of the liver, and more or less prolonged defect or vitiation of the biliary secretion in children, deranging and impairing the processes of infantile digestion and hæmatisation, may be connected with the proximate cause and early phenomena of rickets; but we could not avoid observing, during the treatment of the two first cases of the subject of this

paper, in which great enlargement of the liver was present, that the return to a more healthy size of that viscus, and improvement of the general condition of each individual, and marked amendment of the rickety symptoms, were perfectly simultaneous. The great Boerhaave, it is true, has made the proximate cause of rickets to consist in "a sluggish, cold, and vapid cacochymy, together with a loose structure of the solid parts," which obviously gives to the affection a humoral origin, and places its *ens primum* in the blood; and in this respect Boerhaave is, no doubt, in a great measure correct; but the blood, it should be borne in mind, is dependent for its existence and its continuous healthy condition upon the combined and harmonious operation of a number of organs, the second in office and importance of which is the liver. The first changes wrought upon the food by the vital battery (if we may be allowed such a term) of digestion and sanguification in the abdomen, the chylopoietic viscera more usually denominated, are effected, it is almost unnecessary to observe, by the offices of the stomach; the second by that of the liver. Is it unreasonable to suppose, then, that if this latter organ should become diseased or defective in function, and continue so for any lengthened time during infancy, the period of most tender growth and conformation of the individual, it must effect in some very obvious manner the process of assimilation and healthy organic formation throughout the entire system? Look at a child the subject of slight taint, or what you might consider as the state of commencing rickets. Criticise its entire condition. Does it not bear a strong resemblance, in many points, to that of an adult whom one would suspect to be labouring under some chronic concealed affection of the liver? So has it, in fact, not unfrequently struck our observation. At all events we are firmly of opinion that the practitioner who will view the infantile affection now under consideration as one simply of hepatic disease, with more or less aggravated derangement of all the digestive functions, and so apply his remedies judiciously in accordance, will be he who is most likely to benefit, and *in all respects improve, the condition of his patient.* From some little atten-

tion we have occasionally paid, as opportunity offered, to the indispositions and disorders of children, we will take upon us to observe that there is a pretty comprehensive class of chronic digestive affections, which these tender young creatures too frequently suffer from, the pathology of which is still a subject but imperfectly understood, and the treatment, as a matter of course, uncertain and unsatisfactory. In this class we place the different lesions and perversions of assimilation and nutrition as exhibited in the respective manifestations of scrofula of the vascular, muscular, and osseous structures. We coincide in opinion, it is necessary to observe, with some authors of creditable authority, who consider the malady of rickets, as regards the softness of the muscles and bones, as nothing else than a scrofulous affection of those parts. We also attribute to a taint of the same distemper the dropsical diseases of chronic hydrocephalus and spina bifida, as we are fully convinced these morbid conditions always originate in this peculiar diathesis of debility. Sir Astley Cooper, whose name we always quote with pleasure, has recommended the best measures, dietetical in particular, for the treatment of scrofula with which we are conversant. They are, we conceive, so correct and accordant with sound therapeutics, that we will venture to predict no future experience, founded on right observation, will ever find them much in error. It is the fibrine and red globules of the blood that give to it the power and means of sufficiently nourishing our organs, and of developing and supporting good health and robust strength throughout the system. Sir Astley having rightly noted that the blood of scrofulous individuals was serous and attenuated, and deficient in those important constituents, prescribed the means most likely to obviate such a state, and better its condition. To a child labouring under scrofulous debility or disease, he enjoined the use of animal food three times a day, namely, at breakfast, lunch, and dinner, and the last of these meals was to be taken at 3 o'clock P.M.; warm clothing, with frequent exercise in the open air, when wet, damp, or very cold weather did not forbid; the urging of the functions of the liver and digestive canal once a week by the administration of a

colative and alterative powder of calomel and rhubarb. This is, we truly believe, the best plan of treatment that could be devised for counteracting in childhood, or, indeed, at any period of life, scrofulous diathesis, or tendency to such a state in the economy, and for preventing the development of scrofulous abscess and ulceration locally. Many a surgical incision, sore, and abscess, with such therapeutics prevent from injuring the otherwise marvellous beauty of many a female neck*. There is an error, in our opinion, abroad, of no little evil operation, in some instances, as regards the use of animal food. With a great many individuals, notwithstanding what the advocates of vegetable and farinaceous aliment may say to the contrary, this article of diet is unquestionably taken too sparingly, or its use is not properly timed. The presence of animal food in the stomach at an early period of the day, acts, with many persons of peculiar temperament and constitution, not only as an efficient remedy in soothing and allaying general irritability, and vascular over-action dependent thereon, but it also performs the part of an anodyne and agent of cure in various dyspeptic neuralgias and irritations. Does not the following fact, which, with some others very similar, lately came under our notice, corroborate to a considerable degree these observations? A young gentleman, who had suffered much from gastrodynia, accompanied with a feeling of cardiac distress and sense of sinking at the pit of the stomach, which generally came on between 10 and 11 A.M. (sometimes it was experienced immediately on getting up, between 7 and 8) and continued more or less severe until between 2 and 3 P.M., his usual time of dining. For the cure of this gastrodynia, by the advice of several eminent physicians, he had had recourse to a variety of medicines.

* Whatever measures it may be in the power of the physician or surgeon to suggest, that will preserve from any degree of injury and deformity the most quietly beautiful part of one of the most beautiful objects in nature, must always, we imagine be a matter of some little interest to all. "Observe that part of a beautiful woman where she is, perhaps, the most beautiful, about the neck and throat, the armpits, the softness, the even and marvellous skin, the variety of the colors, which is never for the smallest space the same, the deceitful maze through which the cunning eye strives giddily, without knowing where to fix, or whether it is carried."—*Philosophical Inquiry into the Origin of our Ideas of the Sublime and Beautiful.*

He had made trial of the extract of stramonium and extract of belladonna, of the oxide of bismuth, the oxide of iron, and of the sulphate of quinine, and some other remedial agents of less note, without having experienced any permanent benefit. When he consulted us, his countenance was pale, lean, and anxious; he was thin and somewhat irritable and nervous; his system generally had the appearance of being insufficiently supplied with blood; the pulse was rather frequent and contracted (contracted, we mean, as to the circumference of its vessel); his appetite was pretty good; the bowels were stated to be regular, and his sleep undisturbed. In the course of our inquiry into the symptoms of this case, we put the question to our patient—When do you generally observe the pain of stomach to cease? "Soon after dinner, towards the after part of the day," he replied. How often have you been in the habit of taking animal food in the day, we inquired? "Once," he replied, "at dinner." What do you breakfast upon? was our next interrogatory. "Bread-and-butter, with tea or coffee, and sometimes an egg," was the answer we received. We then prescribed a mutton-chop, with an egg, or good large slice of ham and an egg, with his usual tea and bread-and-butter, for breakfast; and the second morning after taking the mutton-chop as prescribed, the young gentleman, to his no little delight, and the gastrodynia, which had been the bane of his comfort for years, parted company, and have never since renewed acquaintance. When we last saw this patient, more than two years from the time we had prescribed for him, he still continued to take a little animal food for breakfast, and he remained free from the pain. What was the nature of this gastrodynia, then? Was it the instinct or sensation of hunger, idiosyncratic and morbid in this instance, being in the human subject, but similar to that which is naturally experienced by some of the lower carnivorous animals, the beasts of prey, and which urges them so ferociously in quest of flesh, which no other sort of food has the property to allay*. We

* "In the course of this treatise we shall have frequent occasion to remark, that the diseased state of an organ in the human body is the physiological or healthy condition of the same organ in other animals.—*Andral's Pathological Anatomy*, vol. 1. page 94." Translation by Drs. Townsend & West.

could adduce other instances, if necessary, equally illustrative of the good effects of a little solid animal food being presented to the stomach at the morning repast, or at a less early hour of the day, in raising the system from a state of ill health and debility, and conferring upon it the inestimable blessings of good health and strength. It is only, we will here remark, the unhealthy and infirm that ought properly to be accounted poor.

The health of the honest peasant, or labourer of any description, is his wealth, and the happiest wealth or capital, too, in all respects, which he can possess. With none other certainly does he embark so cheerfully in the business of existence, and enjoy with such fulness the fruits of his exertions, or, when they chance to come, the bounties of fortune. With none other can he contribute to the continuance of the constitution and vigour of society, in the renewal of the youth and bloom of population, by raising up around him offspring and issue ruddy with life and the light of youthful health—the *lumen purpureum juventæ*—such objects as his heart always owns and exults in, and his bosom fondly cherishes; and through which thus, by the divinity of parental affection, transmutes, it might be said, by a beautiful alchymy in the moral economy of humble life, the labourer's daily industry and toil into a daily hymn of silent happiness and content, not less acceptable and grateful to the Creator than are the most loud and lengthened orisons of the more indolent and inactive, yet dutiful and holy saint. But to return for a little to the more immediate subject of our paper.

In looking over the observations of the great surgeon, Cooper, upon the malady of rickets, we find that he places the proximate cause of that disease in the mesenteric glands, and thus identifies in a great degree *tabes mesenterica* with rickets, although the affections are unquestionably, we think, distinct both in their origins and symptoms generally. In none of the cases we have described in this paper could we detect any enlargement of the glands of the mesentery, or any tenderness on pressure of the abdomen over these vessels. *Tabes mesenterica* in the infant is more allied perhaps to the affection of atrophy in the adult, than to rickets.

Some time in the autumn of 1837,

we published a short paper in the MEDICAL GAZETTE, in which we pointed out the existence, and described the characters, of a murmur or sound accompanying the cerebral circulation in certain conditions of cerebral disease in children. We took occasion then to state that we thought such auscultic phenomenon, when present in the head, might either be received as a premonitory symptom of chronic hydrocephalus, or as a diagnostic sign of the actual existence of the disease in its most incipient state. This murmur was present, as we have seen, in various intensity, in all the four cases which form the subject of this paper, and we still rest in the opinion we took up on first observing it, that it is always concomitant with, and produced by, a morbid action of the vessels of the brain, which precedes and accompanies more or less dropsical effusion in that organ. As the phenomenon is undoubtedly one of some little interest and diagnostic novelty in the cerebral pathology of children, we would willingly direct the attention of other observers to it, in hopes that it may be found of some utility in indicating the best mode of treatment in the earliest stage of chronic hydrocephalus. Fine though it be “that nothing lives ’twixt it and silence,” we take some little credit to ourselves for having been the first in this country to observe and describe this sound, and auscultic sign of disease, in the encephala of children. Shortly after the publication of our description of the phenomenon in the MEDICAL GAZETTE, one of the medical reviews* disputed our claim to originality in its observance, by the statement that we had been preceded in the matter by an American physician. We do not doubt the truth of this statement of the Review, but we have not yet seen, let us mention, a description of the phenomenon by other pen than our own. We might extend our observations here much further, but this paper has already, we perceive, grown to some considerable length.

43, Sackville Street.
May 10th, 1843.

* The British and Foreign Medical Quarterly, we think.

CONTINUATION
OF THE
CASE OF ILEUS,

Recorded in the MED. GAZ. for April 28.
AND THE POST-MORTEM APPEARANCES.

MAY 1st.—During the past month he had slept well, and ate moderately; the alvine evacuations two or three a day, loose, and yellow; but the extreme emaciation had continued.

4th.—It is stated that for the last two or three days he has eaten but little, that he felt a pain yesterday on the right side. He now complains of griping pains below the umbilicus, where the abdomen is swollen and tympanitic. Pressure on the right side between the ribs and crest of the ilium gives pain. The pulse small and weak; extremities cold; perspiration on the face; tongue, far back, rather coated. Sick once.

Administ. Enema Sapon.; soon returned.
R. Haust. Rhei et Mag. Carb. stat. sum.

10 P.M.—No evacuation from the bowels; griping pain in the abdomen continues.

Adm. Enema Sap.; returned.
R. Ol. Ricini, ʒss. 3tiis. hor. sum.

5th.—No evacuation from the bowels; nausea; pain over the whole abdomen, which he dreads to have touched; laborious thoracic breathing. No wish to live.

He died at 6 P.M.

Post-mortem appearances.

The contents of the bowels.—Upwards of two quarts of a brown fluid, with castor-oil, were found in the cavity of the abdomen. The convolutions of the small intestines, just below the umbilicus, were much twisted and matted together, so as sufficiently to account for the strangulation of the bowels. On the mucous surface the canal in two places was so contracted and blocked up by adhesions as scarcely to admit the passage of a probe. A portion of the jejunum was greatly distended, with a diameter of at least three inches, and lay in front of the ascending colon, which was closely contracted. In this distended portion, between the ribs and crest of the ilium, there was an opening just sufficient to admit a probe, and

taking a course of about half an inch through the coats of the bowel, which were much thickened by deposits of lymph. Near this opening on the serous surface was a conical deposit of lymph two inches from base to apex, at the base of which on the mucous surface there was a cicatrix.

POLYPOID TUMOR IN THE
TRACHEA.

To the Editor of the Medical Gazette.

SIR,

SHOULD the following case be deemed sufficiently interesting to your numerous readers, you will oblige me by inserting it in your valuable journal.

I am, sir,

Your obedient servant,

J. H. STALLARD,

New Street, Leicester,
May 9, 1843.

M.R.C.S.L.

Martha Butler, æt. 40, married, was admitted into the Receiving Ward of the Leicester Workhouse, on Tuesday, April 25, 1843. She was in a most destitute and dirty state, and was labouring under symptoms of bronchitis. Her filth entirely precluded a minute examination; but she stated that for a long time past she had been asthmatical, and had had a very bad cough, but that this cough had been much aggravated by privations and exposure. She was ordered to take the following draught every four hours:—

R. Syr. Papav. Albi, Tr. Scillæ, aa. ʒss.;
Liq. Ammon. Acet. ʒiij.; Mist. Ammoniaci, ʒj. M. ft. haust.

April 28th.—During the last few days she has been much better; her cough is not so violent, nor her dyspnoea so urgent.

29th.—She went to bed as usual last night, but awoke about eleven o'clock, and had a violent paroxysm of coughing, which continued for upwards of an hour. She then got out of bed, and whilst sitting by the side of the bed died before any assistance could be obtained.

Sectio cadaveris 36 hours after death.—The lungs were emphysematous. The smaller bronchi were healthy, but the right and left divisions were highly congested. In the trachea was found a loose body of a polypoid nature, about

the size of an almond, and having a pedicle about three-quarters of an inch long. The trachea at its lower part was much congested, and about an inch and a half below the cricoid cartilage, on the left side, the mucous membrane was considerably thickened and inflamed. About half an inch below the cricoid cartilage, at the anterior part, were the remains of the pedicle of the polypus; and above this point the trachea presented the natural appearance. The stomach was small and contracted. The liver on the whole larger than usual; it consisted of twelve or fourteen lobes, varying in size from a nut to a large orange; the larger ones, three in number, corresponding with the right and left lobes and the lobulus quadratus: in structure it appeared healthy. The kidneys and spleen were very large. The uterus was carcinomatous.

REMARKS.—When the patient was admitted, I saw no reason why a favourable prognosis should be withheld, knowing how much the comforts, cleanliness, and dietetics of the workhouse, usually accomplish in these cases. I was surprised, therefore, at the sudden termination in death, and was anxious to obtain further information as to its cause. Polypoid tumors in the trachea, so far as I have read and seen, are exceedingly rare. M. Andral states, that hypertrophy of the mucous membrane may be confined to a circumscribed spot, and produce there a tumor projecting more or less above the level of the surrounding membrane; but, he continues, they have been oftener met with in the larynx than in any other part of the air-passages. (Translated Pathology, p. 472.) I was at first inclined to doubt its origin from the tracheal mucous membrane, but the remains of the pedicle, and the thickening of that part of the membrane against which the tumor would rest, left no doubt on this point, and the separation of the tumor, produced probably by the violent coughing, was the cause of the sudden death.

CICERO.

LUNATIC ASYLUMS.

No department of the practice of physic can boast so great a progress within the last few years as the treatment of insanity; and it is with a particular pleasure, therefore, that we ever and anon comment on the reports of our great lunatic asylums, as they issue from the press. It is true that, as far as regards the medical part of the treatment, the improvement consists rather in the abolition of the false than in the establishment of the true. The stated bleedings and vomitings of the last generation have disappeared, like the scourgings and the hellebore of earlier times, and have left no fixed practice to succeed them. The physician prescribes for the symptoms as they arise, he gives carthartics to the constipated, and morphia to the restless, but there is no longer any specific for madness. Neither the Anticyra of the ancients, nor "the dark house and whip" of Shakspeare's age, will cure the disease; what *will* is a problem yet to be solved. But it is some satisfaction, at any rate, to find, in Thomas Carlyle's language, that old false formulas are trampled into destruction; the ground which they occupied, though now bare and desolate, may yet serve as a foundation for truth.

In the mechanical and moral treatment more has been effected. For, besides the abolition of chains and strait-waistcoats, which may be considered as merely negative improvements, abstaining from bad rather than introducing of good,—farm-work and manual trades, books, music, and

various games, form part of the system in well-regulated mad-houses.

Perhaps some fortunate reasoner may succeed in curing the erring mind by a direct method, correcting the hallucinations of one sense by the evidence of the rest; till this happy era arrives, the physician must content himself with an indirect one. The mind of the lunatic must be withdrawn from its favourite contemplations by the allurements of other and safer objects. An asylum may be advantageously turned into a school, where the inmates are withheld from the airy nothings of their imagination; and as they advance in arithmetic, geometry, or languages, they will forget the sprites who tormented them in their ignorance. In the last annual report of the Glasgow Asylum (from which we gave an extract a few weeks ago) it appears that printing has been lately added to the previous employments of the patients. The first product of this press was a periodical, which went on vigorously for ten weeks, when it dropped, from the discharge of some of its contributors. Since then the press has been busied with other matters; and Dr. Hutcheson, the reporter, anticipates that it will not lack occupation for the remainder of the year.

The boldest proposition which he makes, and in which it is difficult, or rather impossible, to agree with him, is, that every one labouring under hallucinations must be locked up, whether mischievous or not.

"When an individual imagines himself to be a supernatural being, to be favoured with divine revelations, to be commissioned to redress grievances, to have suffered or to be threatened with injury, to be conspired against, or to be poisoned, he is *dangerous to the lieges*; and, however calm he may seem, however sane he may appear to be on other subjects, however careful and prudent, however acute he may be in business, or skilful in the exercise of his profes-

sion, he ought not to be suffered to remain at large, but ought instantly to be placed under treatment and control."

This is a sweeping clause indeed! "If we shut up every woman who changes her mind every minute," says Dr. Smith, in the novel of 'Discipline,' "who is to make our shirts and puddings?" And if we desire to shut up all who are included in Dr. Hutcheson's comprehensive schedule, who will build asylums enough? Not the men of Glasgow, assuredly; for they are too tardy in subscribing for a single one. Whole classes of religionists, if we mistake not, imagine themselves favoured with revelations, and would demand towns metamorphosed into asylums for their reception. Authors against whom Paternoster-Row conspires, and householders constantly ill treated by their ungrateful servants, might swell the crowd, and embarrass the mad-doctors with a superfluity of employment.

The fact is, that Dr. Hutcheson has got into this scrape from an unwillingness to concede that monomaniacs are amenable to the criminal law. If we once allow that the distemperature of Macnaughten's mind, for example, rendered him an irresponsible being, and made a cell in Bethlem his extreme punishment, it will be necessary to shut up these possible criminals by the thousand. But if we admit this dangerous plea in those cases alone where the maniac is so mad that he cannot see the link between murder and the gibbet, these quiet lunatics will remain at large, and society will be satisfied to trust to the law for security. Monomaniaes, in short, will yield to social discipline, backed by Newgate and the gallows, just as they submit to asylum discipline, backed by the belt, the gloves, or a dark cell. But still some portion of danger will be left? No doubt of it. Neither law nor custom

authorises us to guard against every possibility of danger; it is urgent and immediate danger alone which would justify us in imprisoning a myriad of eccentric fellow-subjects. But the juries must do their duty. It was said by Burke that trial by jury was the soul of our constitution, and that the object of all law and government was to bring twelve honest men into a jury-box—on the supposition, however, we would add, that the twelve honest men aim at the real, and despise the fantastic. Not a week has elapsed since a jury acquitted the mischievous lad who snapped a pistol at the clergyman officiating in St. Paul's. The alleged motive of the culprit was his indignation at hearing a usurper prayed for instead of James Stuart; so that he would seem not to have been in possession of his senses, and according to different theories, might have been a fit tenant for Newgate or Bethlem. The former would have been the better alternative for society; but even the latter would have been far preferable to the total impunity which the prisoner enjoyed by a simple verdict of acquittal.

The influence of hereditary predisposition in producing madness is evidently considerable; and is proved not only by common observation, but by the records of lunatic asylums. But what is the influence of marriages between relations, without hereditary predisposition? The general belief is, that they are likely to produce imbecility in the children; but whether this belief rests on a sufficient number of facts we know not. It is, at any rate, probable that repeated intermarriages between blood relations, or breeding in and in, as the graziers call it, will cause a speedy degeneracy of mind and body; and it is to be lamented that political considerations make this practice so general among the sovereign houses of

Europe. It certainly is not the way to make kings *ablemen*, which, according to Mr. Carlyle, they are etymologically, and should be really. Of these repeated intermarriages Dr. Hutcheson goes so far as to say, that "imbecility, or idiocy, is the ordinary result; but positive madness is not an unfrequent occurrence."

He thinks that physical and moral education might be so managed as to be a powerful preventive of insanity; and no doubt he is in the right. But when he adds that this requires no sacrifice of the passions and prejudices of mankind, we believe that few will agree with him. We rather side with what he says further on, that the task which he proposes is difficult in the extreme, but that the issue will reward the labour. Among the minor and more obvious duties of him who endeavours to give a sound mind to the children of parents who are nearly or quite insane, will be a judicious abstinence from over-instruction. For the first seven years of life, at least, the hours of study should be few and far between; and we would add, that when the years for real study have come on, the exact sciences should form a considerable portion of the child's education. In the records of an asylum where poets and artists abounded, Pinel could not find a single geometer.

Intemperance and want are frequent causes of insanity; and at Glasgow they are unfortunately both on the increase. Want produces despair, and despair seeks a temporary consolation in drinking. Religious terrors are another common source of madness; and the intrusionist question, half shared between religion and politics, has of late produced a good many cases at Glasgow.

In some cases the state of the patients admitted had been made worse by bleeding, which is still popularly

supposed to be a prime remedy in mania; and a yet more frequent error is the abuse of drastics, low diet, and tartar emetic.

This report, which is benevolent in its tone, and judicious in many of its suggestions, has confirmed us in the opinion which we offered some years since, that the more opulent inhabitants of Glasgow are so sluggish in their subscriptions, that to relieve the misery of its poor a rate should be levied on the town. The asylum now building cannot, it seems, be completed at present to contain 600 patients, but must be opened when ready to hold 350; though the sum required for the larger number would have been by no means enormous. The directors, indeed, boast of their economy, and contrast their expenditure with that incurred in building lunatic asylums in Ireland, where the cost has been greater, though the wages of labour are less.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

May 9, 1843.

THE PRESIDENT IN THE CHAIR.

Observations on the Medicinal Properties of Indian Hemp. By JOHN CLENDINNING, M.D. F.R.S.

THE author commenced his paper with general observations on the importance of narcotics, but especially of opium, in the treatment of disease. After having referred to numerous examples of the successful use of opium in acute and chronic disease, he adverted to the inconvenience occasionally attending the employment of opiates, especially to the derangement of the stomach and bowels and kidneys, and the vertiginous and other painful conditions of the nervous system they so frequently produce. He then stated that, in his experience, those inconvenient effects had occurred so frequently, and been found in many cases so difficult to obviate, without the abandonment of the use of a class of remedies of the utmost importance in a large number and variety of diseases, that he had been recently induced to make trial of the extract of hemp, recommended by Dr. O'Shaughnessy, of Calcutta, as a substitute for opium in numerous instances. The author's object in

making this communication was to bring under the notice of the Society the results he had obtained, as in his judgment important to be made generally known with a view to further and more extended trials by other practitioners, more especially at this moment, when there was some prospect of a new edition of the London Pharmacopœia, upon which he understood a Committee of the Royal College was actually engaged.

The author then gave details of eighteen cases, from a much larger number, in which he had given trial to the new remedy with satisfactory results.

These trials included cases of acute and chronic disease, in persons of both sexes, and persons of very various ages. The number of cases detailed, although necessary to substantiate the claims advanced by the author in favour of the new narcotic, was yet such as to preclude any analysis of them in this place.

It will be sufficient to say generally, that the indications for its use in these cases appear to have been more especially to relieve neuralgic pain; to relieve irritation and spasms of chronic bronchitis, of rheumatism, &c.; and to subdue sleeplessness or disturbed rest from whatever cause, if not arising from inflammation in the head. The author found the remedy highly useful in checking cough in phthisis, and cramp and irritation in the limbs, &c. in rheumatism, without any interference with the digestive processes, or intestinal action or secretions, yet with an anodyne and hypnotic effect not less uniform than that of opium. He gave it trial also in several cases of low fever, characterized by spots, tremors, and delirious restlessness, and with very good effects; it repressed delirium and conciliated repose, and thus secured that tranquillity and refreshment the proper effects of sleep. He reported also some instances of successful use of hemp extract, as a pure anodyne to secure sleep, by suppressing pain, arising in one case from a cut, in another from a violent purgative, and in a third from rheumatic irritation of the meninges.

The author concluded his paper by a *résumé* of the objects of his trials, and the results and conclusions he had attained.

He stated that his experience had satisfied him that the hemp extract was possessed of medicinal properties sufficiently energetic and uniform to entitle it to admission into our national Pharmacopœia amongst our most useful narcotics; and that as a substitute for opium, especially in cases for which that drug was unsuited, owing to idiosyncrasy, or to the presence of active indigestion, or the nervous temperament, he had found reason to place much confidence in the extract, and to regard it as a remedy exceeding in value that of any other narcotic, or

combination of narcotics, with which he was acquainted.

On the Removal of Blindness depending upon Palsy of the Iris. By ALEXANDER URE, Esq. [Communicated by the PRESIDENT.]

The author described the case of a female patient, who had come under his care at the Western Eye Dispensary, in consequence of having been suddenly attacked with blindness in one eye. The pupil was dilated and immoveable, and she was wholly unable to distinguish light from darkness. Judging the case to be one of idiopathic palsy of the iris, the author proceeded at once to employ the method of cauterizing the circumference of the cornea by nitrate of silver, first proposed by Serres. The result was prompt restoration of sight. He pointed attention to the importance of discriminating accurately between palsy of the iris and amaurosis; since the treatment which is so efficacious in the one would be no less improper than useless in the other.

On the Sugar in the Blood in Diabetes. By -Dr. BENGE JONES.

The very delicate test for grape sugar which was communicated to the Academy of Sciences in Berlin, in 1841, by Professor Mitscherlich, as the discovery of Herr Trommer, was applied by him without success to the examination of diabetic blood. He found, however, that if $\frac{1}{1000}$ of grape sugar was mixed with blood, the test would indicate its presence. An opportunity occurred to the author of this paper of repeating the experiment on the blood of a diabetic patient of Dr. Nairne's, in St. George's Hospital. The disease was of about a year's standing, and the patient was in other respects in tolerable health. On the 24th of January, 1843, he was bled to twelve ounces, three hours after a dinner of bread and meat. The following morning the blood was well separated; the serum milky; the clot slightly buffed and cupped: specific gravity, $\cdot 1029,7$. The serum became clear when treated with æther, and the test for grape sugar gave a negative result, as the precipitate which first formed did not redissolve, and only became much darker when heated, partly in consequence of the deep purple colour which is formed by the action of caustic potash and sulphate of copper on fibrin or albumen.

The albumen was therefore removed by evaporating the serum to dryness in a water bath. The residue was finely powdered, treated with water, filtered, and tested for grape sugar. The characteristic changes then took place. The clot of the same blood

was treated in the same way, and the test showed that grape sugar was present in it also. The urine passed between three hours before the bleeding, and nine hours after, was five pints, specific gravity, $\cdot 1031,3$, and when tested by the same method the liquid first became blue, and then a very large precipitate formed, which was at first bright yellow, and after some hours became dark green.

Uric acid alone does not form the clear blue solution, although, when boiled with the potash and sulphate of copper, it will produce the same coloured precipitate as the grape sugar does.

BIOGRAPHICAL NOTICE OF THE LATE T. FAWDINGTON, ESQ.

(From a Correspondent.)

DIED, on the 21st ultimo, at Manchester, Thomas Fawdington, Esq. in the 48th year of his age.

The loss of this excellent surgeon and truly upright man will long be felt by those who enjoyed the privilege of his society and friendship. Possessed of an untiring zeal for the advancement of his profession, whose resources on several occasions he contributed very materially to extend, he was no less distinguished amongst his brother practitioners for the unflinching honour and integrity which ever characterized his intercourse with them and the public at large. He had been engaged in active practice for a period of about twenty years, the greater portion of which was most laboriously devoted to the cultivation of morbid anatomy, regardless alike of the sacrifice of much personal comfort, and large pecuniary expenditure involved therein. A lasting monument of these labours has resulted in the formation of a very extensive museum,—rich in almost every variety of diseased structure, but peculiarly valuable with reference to the several morbid changes of which the bones and mucous membranes are the seat. A Catalogue of all the specimens has been published, containing, in relation to very many of them, a brief but luminous sketch of the principal symptoms observed during the progress of the several diseases, of which the former are the products. The osseous preparations are most beautifully displayed, comprehending a very perfect series, from those which exhibit the anatomical structure and nutritive process of healthy bone (all very minutely injected) to the appearances observed after fracture, and the means employed by nature for its reparation. But it is to the pathological specimens that the merit of excellence pre-eminently belongs. In these is comprised almost every variety of morbid change of which the osseous

structure is susceptible; and the extremely beautiful and striking manner in which they are severally preserved, affords a ready clue to their elucidation. Amongst these I may briefly allude to a preparation of malacosteon of the pelvis, the singularity of which consists in its having occurred at an advanced period of life, viz. seventy-three, the woman from whom it was removed having previously given birth to a numerous family without any difficulty or delay in the process. Amidst much that would amply merit a more detailed notice, but for its too great encroachment upon your space, it would be wrong to omit all allusion to the extensive and truly interesting series of preparations illustrative of the healthy and diseased conditions of the mucous membranes. The nature of the changes which this structure undergoes in disease was ever a favourite subject of investigation with the late Mr. Fawcington; and I have little hesitation in affirming, that, under this head, there does not exist any collection more valuable, either in point of intrinsic excellence, or in the completeness by which every link in the chain of morbid products, as applicable to the above structure, is characterized. To most of the specimens is appended a succinct history of the symptoms observed during life; and what considerably enhances their value is the circumstance of coloured drawings having been made with the utmost fidelity from the parts in a recent state, by which the otherwise evanescent characters of disease are made to stand out in prominent relief.

About seven years ago Mr. F. was elected to the important office of surgeon to the Royal Infirmary, an appointment most congenial to his wishes, and associated with many of the happiest reminiscences of his medical career. For a considerable period prior to this appointment, he had filled the chair of anatomical lecturer at the late School of Anatomy and Medicine in Marsden Street. In this capacity he was very successful in diffusing considerable interest over a subject too frequently regarded as destitute of this quality; and by those students whose privilege it was to hear him, his valuable prelections will not readily be forgotten. As a writer, Mr. F. was very favourably known to the professional public. His "Case of Melanosis," illustrated by many very accurate and beautiful drawings, published at a period when the pathology of that singular disease was but imperfectly understood, gained him no inconsiderable celebrity; and I am not aware that, up to this time, any thing very material has been added towards the more complete elucidation of the phenomena of that morbid condition. Mr. F. was likewise the author of a very valuable paper on Subcutaneous Nævus,

in which the method of treatment by the seton was vindicated, and several cases, with drawings, adduced to prove the efficacy of the plan proposed,—a mode of cure, which, though not originating with my deceased friend, was at least more clearly and definitely brought to bear upon the treatment of this affection, than had been accomplished by previous surgeons.

Mr. F. was fortunate enough to enjoy a considerable share of public patronage,—an advantage, which, although so far indicative of the estimation in which his professional services were held, was mainly prized for the opportunity thereby afforded him of extending the resources of his art, and maintaining that high sense of honour of which his whole medical career was one bright exemplification. Few practitioners, probably, have descended to the grave more sincerely lamented both by his former patients and his medical brethren, many of whom accompanied his remains to their final resting-place. By his former pupils he was universally esteemed; and the premature loss to them of his valuable counsel and friendship will long cause his memory to be "neither unwept, nor unhonoured."

T. M.

MEDICAL REFORM.

To the Editor of the Medical Gazette.

SIR,

HAVING thus far developed those views of Medical Reform which, in my humble opinion, seem most likely to benefit the profession, and through it the community at large, I must beg your indulgence to one more (and my last) letter on some subjects bearing upon this important question.

First, then, I would beg to draw attention to some anomalies existing under the present system, which, I conceive, would be, if not entirely removed, at least greatly diminished under the system which I have so fully endeavoured to advocate.

The College of Physicians ought to be considered the fountain-head of medical, the College of Surgeons of surgical, knowledge; and, yet, is it not strange that the diploma of the College of Surgeons should long have been considered the only requisite for army, navy, and many other public medical appointments? Although, in the army and navy, especially during periods of war, the number of important and serious surgical cases bears a much larger proportion to the whole amount of cases than occurs in civil practice, yet, taking all periods into consideration, it will be found that a vast preponderance, even of army and navy cases,

falls under the strict province of the physician. Perhaps some one will say, "Yes, but then we have Army and Navy Boards, and the East India Company has a Board, to examine candidates for these appointments, as to their qualification." Surely this is no great compliment to our profession, that the person considered qualified by our Colleges should have again to submit to a test of his competency by an Army or Navy, or East India Company Board. The Bishop of London examines a candidate for deacon's orders; when he takes priest's orders, he may happen to fall under the examination of the Bishop of Worcester: having been duly passed and ordained by these bishops, it would appear to indicate some distrust in them, if, when this gentleman succeeds to a curacy or living in the diocese of the Archbishop of Canterbury, he should be compelled by a further examination to show his competency for such a post. Now, under the plan of medical reform above contemplated, the candidate for army or navy appointments would have acquired such diplomas from the two Colleges as should be thought requisite, and if this were not sufficient, an especial examination might be instituted for such purposes.

This, then, is one of those anomalies that arise out of the present confused state of our profession.

Some time since a doctor was elected physician to a London hospital who was chiefly known to the public as a skilful mechanist and operator in certain deformities. Let it not be supposed that I for one moment doubt the fitness of this gentleman for the office; my observations are not made upon the person, but the system. A very large proportion of provincial physicians possess no kind of English or Scotch diplomas, some scarcely even nominal titles to the office and dignity of a physician. In London, vast numbers of pure surgeons, as they are called, possess no other diploma than that of the London College of Surgeons, and yet their only chance of livelihood is in the practice of medicine. Numbers of apothecaries in the country write Mr. —, Surgeon, over their doors, who have never been inside the College of Surgeons. The genuine apothecary exists, one may almost say, in the shadow of a name,—"*Stat nominis umbra*." A few representatives only of this order remain in London; and what is still more curious, several persons in London, whose sole qualification is that of apothecary, are physicians in reality, if not in name, writing prescriptions, and although unwilling to soil their hands with a pill or mixture, not averse to touching the guinea.

It would be useless to adduce any further *examples of the present confused state of the profession, and its inefficiency to secure*

to its members the rights and privileges of their respective orders.

Something has already been said upon the apothecary system, but I cannot close the subject of medical reform without again adverting to this subject. The great object of the medical profession is to confer the greatest amount of good upon the public; the duty of the government (which is the representative of the public), on the other hand, should be to foster, encourage, and protect us as a learned profession. I am well aware that in attacking the present system on which the general practitioner proceeds I may meet with many who are opposed to my views, upon high principles, and with still more who defend the system from less honourable motives; perhaps, as thinking it holds out the greatest probability of profit. I cannot, however, with propriety, withhold my views, even at the risk of opposition and personal offence, and I must again declare that my sole object is to give my opinion on a plan of reform which shall render our profession more useful, more honourable, and more respected. Let us see how the present apothecary system acts.

It is not for me to say whether more physic is poured down the throats of patients than ought to be; but it is self-evident that the present system offers a premium for such practice; and knowing human nature to be as it is, surely it were wiser to avoid temptation than to court it. Many general practitioners are no doubt above this practice; but, then, what is the result? Instead of being better paid for their honourable disinterestedness, they are not so well paid; and, what is still worse, ranked in the same class with their less scrupulous brethren.

Look, again, at the effect of this system on the scientific study of medicine. How is disease to be studied by the person engaged in making up medicines? How is that man's judgment to be considered clear and unbiassed, who, in coming to the bedside of his patient, is occupied in thinking how much medicine he can send? Indeed, I believe some persons are so sanguine on this point as almost to attribute the union of a fractured limb to an effervescing saline draught every three hours, two pills at night, with a draught in the morning, and an evaporating lotion to the limb.

Suppose a consultation between a physician and a general practitioner. By a consultation I have always felt it to be understood that two persons should consult together for the good of their patient; and, yet, often have I seen an ignorant bombastie physician meet a respectable, well-informed general practitioner, only to swagger and dictate to him as if he were a dispensing chemist, and had no share in the care and

responsibility of the case. On the other hand, the general practitioner may have some pique against the physician, and send in anything but what was agreed upon in consultation. It is to be hoped such things do not often occur, but they may, and do, happen occasionally. Under the system I have advocated they could not.

But a still more serious evil arises out of the present apothecary system, both as regards the public and profession. I allude to the contract system. Let us examine the plan by which the general practitioner contracts to supply the poor of unions and parishes with medical and surgical advice, and medicines, and see how it operates, both for the public and the profession. Driven by competition to undertake this office at the lowest possible salary, the medical man assumes this arduous and important duty, not from any hope of gain, but merely with the object of acquiring private practice, or, if he has this already, of keeping other competitors out of the field. So far the system must lead to perpetual professional bickerings and jealousy. He is necessarily obliged to economise his labour, both in visits and in the form of dispensing his medicines. How does this affect him? The clergyman or squire of the parish, or principal farmer, sees that he conducts a severe case of fever or inflammation, or a bad fracture, to a successful issue in the case of a pauper, with one half the medicine and attendance that is bestowed upon his own family in far less formidable ills. What is the result? He finds it both cheaper and pleasanter to pay a fee or two to a consulting practitioner, or even flies to a neighbouring bone-setter, or to somebody's alterative or cough pills; or he goes to a neighbouring chemist and asks for an aperient pill or draught, or a saline mixture, or "something to comfort and nourish his inside." But how does it affect the poor themselves? This is a far more serious and interesting question! Why, the medical man giving medicines and attendance for a salary that would barely pay for the former item alone, must necessarily too often use medicines defective both in quantity and quality. Let us hope that a high sense of honour and morality may lead many, nay, most parish doctors to be above such considerations; yet, the fact is evident, that human nature is human nature, and there is no check upon such conduct. Certain it is, that the more expensive remedies cannot be often, if at all, employed; and, from my own experience, I have reason to believe that the course of medical treatment so necessary after the subsidence of acute disease, is too often much neglected, and that the order for wine and mutton, though no doubt mostly necessarily, entirely

supplies the place of alterative medicines, tonics, and careful watching. But, supposing the profession is a body so immaculate as to be far above these errors, there yet remains one fault in the present system, even under its present modified and improved form, which is unavoidable so long as the general practitioner combines the sale of drugs with his professional character. Many parish surgeons have no assistants; consequently, many persons must be kept waiting much longer for their medicines than they ought to be. Take, for instance, a case of inflammation, in which it is proper that the abstraction of blood from the arm should be immediately followed by an opiate and the application of leeches—the delay of a few hours may render their use not only less efficacious, but absolutely hurtful. It will be said, "but the poor have the power of complaining of any neglect or mal-practice." To a certain extent they have; but when it is considered that even the richer and better educated classes of society frequently praise or blame their medical attendants upon very unjust grounds, the criticism of the poor upon any other point than the feelings, manners, and assiduity of their professional attendant, cannot be said to stand for much. Besides, they are as confiding, perhaps more so, than others, and they argue, that whatever their doctor does is right. But let the medical man undertake only the professional attendance of the poor, and let a chemist and druggist contract for supplying them with the medicines regularly prescribed by such medical attendant, and then see how much better the interests of the poor would be attended to! Here would be no self-interest to tempt him from the paths of benevolence and duty; his feelings and natural desire to obtain reputation would alike induce him to see that the orders he gave should be both promptly and properly obeyed.

The subject of remuneration for professional services is one on which much cannot be said in a letter chiefly directed to the preliminary considerations of medical reform.

Perhaps it would be well under this system that the fees of the general practitioner should be regulated by law, and constitute a legal debt, because they are most frequently called upon to attend a class of persons who would not consider themselves bound by a debt of honour; but I should be sorry to see the fees of the pure physician and surgeon made a legal debt, because this might in some degree diminish the high position which they, together with the members of the bar, at present maintain.

It would be inexpedient, even in this slight sketch of medical reform which I have ventured to attempt, entirely to omit the subject of quackery. Perhaps no part of the subject

is more difficult to deal with satisfactorily than this; yet I would venture here also to cite the maxim before inculcated, that the great object of the medical profession is to bestow all the good it possibly can upon the public, and that, in its turn, it has a just and fair claim to the respect, sympathy, and protection of that public. In the course of these letters, it has been more than once hinted that the plan of medical reform therein laid down would materially lessen the necessity (if it may be so termed) for quackery, and in so doing it would probably in some measure diminish its frequency. It is hardly to be expected that any arrangements in our profession, in a free country like England, be they ever so stringent or ever so liberal, should be able entirely to put down or disarm the quack of every denomination.

First with regard to what is termed the "counter practice" of the chemist and druggist: this, if not put down by the strong arm of the law, may at least be legally discouraged, and kept within some limitations. The profession, too, being rendered more united and harmonious, would possess great power in this respect, by withholding their prescriptions from persons who were found to be infringing upon their privileges. With regard to more impudent and open quacks, perhaps a negative course would be better than a positive prohibition, the impossibility of which being carried in every case into effect would in time render it nugatory. The quack might be prohibited, under pain of punishment, from putting his name on his door or house as doctor; from advertising, &c.; and he might be rendered amenable to the law for a two-fold action for damages, both to the public whom he may have injured, and to the profession whose rights and privileges he had invaded.

But the most fearful ravages made by the quack, both upon the health and pockets of the people, is through the medium of advertisements. It is to be feared that this source of puffing and notoriety, being one of considerable profit to the government, would not be so readily put down; but let me once more remind them of the claims of a highly useful and honourable profession upon their fostering protection; let me remind them of their duty through that profession of guarding the bodily health, as well as the morals of the people, and let me tell them unflinchingly that that government cannot be altogether sound which hesitates not to derive some portion of its revenue from sanctioning the publication of the most gross and deceptive falsehoods. It is devoutly to be hoped that whenever a measure of medical reform is adopted, some measures may be taken for diminishing, if not annihilating, this at present monstrous and iniquitous system. It *would not be too much, perhaps, to aver,*

that many a quack mountebank has, aided by this system of advertising, realized a larger fortune than a Watt by the invention of the steam engine, or a Jenner by the discovery of vaccination.

A useful combination, or superior mode of preparing many remedies, has often been due to exertions of some individual practitioner, and such remedies have, in after times, been used by the profession under the names of their original discoverers; as, for instance, Dover's Powder, James's Powder, &c. &c. It might be well, in case of any one making a really useful discovery of this kind, that the matter should be laid before a medical board constituted for that purpose, and that the discoverer should receive from government a reward commensurate with the value of his discovery, which should then be made known for the benefit of the profession generally, and through it of the public.

Should this, or any other plan of medical reform, be carried out, so as to render our at present distracted and divided profession more uniform and harmonious, I have often thought that a grand scheme might be adopted of forming a quiet and united club for the benefit of the widows and orphans of medical men. In a profession like ours, in which expenses are certain, and remuneration most uncertain, in which there is no stock in trade beyond an expensive education which dies with its possessor, no salaries, and but few, very few, posts of honour and of wealth, such a scheme, if practicable, would be most desirable. My theory may be Utopian, but if it be, at least let me beg your attention to my dream. We have at present a most useful and most beneficent institution for the benefit of widows and orphans of medical men, but their charity extends only to those who are left entirely, or almost entirely, unprovided for, and that too merely to London and its immediate vicinity. Now a young man, commencing life as a married man, can ill afford to subscribe to such a society, because he says "I am possessed of a few thousand pounds, or I have insured my life for a few thousand pounds; should I die, this provision for my family, however slight and inadequate, will preclude them from the benefits of this society, and at present I cannot afford to subscribe for others' wants; I would willingly do so, but I must wait till I am richer." He goes on plodding honestly and honourably in his profession; he has reared up several children; he is just about to obtain the summit of his ambition; has means sufficient to bring out his children in the world, and to lay by a trifle for his own declining years; when, perhaps a sacrifice to the noble and honourable exercise of his calling, he is carried off, to leave a widow barely provided with decent comforts of life, and without the means to carry on that edu-

cation of his family which his professional exertions had enabled him to commence. The plan I would propose is, that every person on entering the profession should be compelled to pay a fee to a society to be called, let us say, "The Society for the Widows and Orphans of Medical Men, and also for Decayed Medical Men." The entrance fee should be compulsory, and let each person afterwards use his own discretion to continue a subscriber or not, according as he likes, or at any period of life, to enter the society. The annual payments could be regulated according to age, health, &c. as in the ordinary assurance offices. The benefits of the society only to be extended to subscribers, at least their widows and orphans, and to themselves when in old age or infirm health. This benefit to be properly apportioned, and not to be given at all to persons whose other means exceed a certain income. In the present philanthropic age, no doubt such an institution would, ere long, receive liberal donations, legacies, &c. from some of our wealthier professional brethren, and no doubt also from many not of the faculty.

I have, now, sir, brought to a close my humble views on the subject of medical reform. I would willingly linger one moment longer to tell the public that we deserve their sympathy and support. From an early age we are devoted to those studies, which would repulse many a sensitive mind; and if we are buoyed up with the expectation of some share of wealth and honour, yet are we supported by far higher and more noble views: we have the disgust of the dissecting-room to read those pages in the history of nature that are to benefit mankind; we lean over the sick, pestilential bed of the pauper to reap no other reward than the conscious satisfaction of doing him service, and of acquiring that knowledge of disease which is to render us useful to our fellow-men. If in after life we reap some reward of our labours we may fairly say, "Thou shalt not muzzle the mouth of the ox that treadeth out the corn;" and this reward at the expense of how much mental as well as physical exertion is it not acquired? As individuals we have no complaint to make, it is the fortune of many of us to be rewarded, respected, and esteemed! It is for the medical profession as a body that I would claim the public sympathy. As a body we may be said to be almost entirely unrepresented. Our general want of wealth, our laborious professional occupations (and these, too, coming late in life), preclude us as individuals from seeking to represent our profession in the House of Commons. From the House of Lords we have been excluded. An occasional baronetcy may shed honour upon our profession, but so far from giving ease and

leisure to its possessor only requires of him increased energy and exertion to enable him to leave no empty encumbrance of honour to his heir.

Look at the present improved state of medical and surgical knowledge and practice! Look at the mass of poor to whom our services are daily given! Look at our army and navy medical officers, and say whether, as a body, we are not deserving of better things? It is truly pitiful to see that one little action may place a soldier or sailor in the path of wealth and honour; whilst very many years spent by the medical officer in the arduous and honourable prosecution of his career, exposed not only to the dangers of war, but of fever, dysentery, and plague, will barely earn him a paltry pension.

I must apologize for having trespassed at so great a length upon your columns, and

I remain, sir,

Your obedient servant,

PHILOMETHES.

REFORM ASSOCIATION.

To the Editor of the Medical Gazette.

SIR,

ALLOW me to call your attention to the proceedings of the North of England Reform Association, at the late meeting of this body at Sunderland, as you will find them reported in the Northern Advertiser or Gateshead Observer of last week.

You will find, that while the highly-respectable president of the association, in his opening address, insists upon the necessity of grades and divisions of labour in the profession, and the propriety of supporting such grades and divisions by legislation, the report of the council expresses a somewhat unqualified approbation of the views of Sir James Clark, who would legislate only for one uniform grade, and leave the others to chance, or rather to the caprices, selfishness, and carelessness of the various Universities, British and foreign, which now undertake to give or sell degrees.

It is true that the report, and a petition also presented by the council, assert the propriety of uniformity in the qualifications on which the various honorary degrees are to be granted; but certainly the council does not take that care to express its opinion, free from ambiguity, which is displayed by the president.

The same general proposition which is stated by the general practitioner when he wishes to be distinguished from the quack, includes the utility, nay, the necessity, of grades and distinctions in the profession; and, in my opinion, the man who contents himself with asserting the propriety of legis-

lating for one grade only, is no true medical reformer.

The only argument offered by those who contend against grades, which is worthy of the least consideration, is, that the various subjects of medical science are closely connected,—that it is difficult to point out the bounds which separate medicine from surgery, and so forth. We admit the utility of medical knowledge to the surgeon, and of surgical knowledge to the physician; we likewise conceive that it is impossible to point out the distinctions or exact divisions between the animal and vegetable kingdoms, and that a general knowledge of both is highly advantageous to the man who devotes himself to the study of either; but we are convinced that De Jussieu or Robert Brown, or Cuvier or Owen, is a proof of the utility of division of labour in a science not more vast than medicine, and where the path of the student is more discernible than in our science.

It appears to me that the branch system of medical legislation has been too little considered. The grades of druggist, general practitioner, doctor of medicine, and doctor of surgery, would realize the most appropriate scheme that can be conceived. After the degree of general practitioner had been obtained, I would allow an additional amount of time of study, passed in hospitals and at universities, or a certain time spent in private practice, to qualify for examination for the higher degrees.

Such is the general outline of the scheme of medical reform conceived by a young physician; and after all, sir, I think you will grant that we young members of the profession are more concerned in the matter than the old practitioners.—I am, sir,

Your obedient servant,
ROBERT MORTIMER GLOVER,
M.D. Edinb.

Newcastle-on-Tyne,
May 1, 1843.

PATHOLOGY OF THE BRAIN.

To the Editor of the Medical Gazette.

SIR,

THE profession are highly indebted to Dr. Burrows for the light he has thrown on the pathology of the contents of the cranium, in his recent lectures before the College of Physicians; for although most practitioners will, like myself, find that their practice has been in accordance not only with the facts he has brought forward, but with his deductions from them, yet it is no small satisfaction to have the results of individual experience thus agreeing with the theory of the most observant pathologists. Dr. Burrows' observations seem the more important at the present time, when some of your

recent correspondents have been anxious to do away with depletion in apoplexy, arguing against its use from the instances of its abuse; and perhaps influenced by the theories of Dr. Abercrombie and others: indeed the authority of such a man as Dr. Abercrombie, if in error, cannot be unattended by injurious effects.

These remarks are, however, so obvious, that I should not have troubled you with them had it not appeared to me that neither Dr. Burrows, nor (as far as my knowledge goes) other observers, have taken sufficiently into account the probability that an elastic serous vapour, existing between the layers of the arachnoid, and perhaps in other parts, performs an important office in equalizing the pressure on the solid contents of the encephalon. It does not seem to me that any resiliency of the medullary mass, nor the varying quantity of extra-vascular serum, will satisfactorily account for all the phenomena, without supposing the presence of an elastic aeriform fluid: the existence of a vapour or halitus arising from the serous membranes (spoken of generally by modern anatomists) seems equally necessary, and its existence at least equally probable, in the head.

I hope that Dr. Burrows will not deem this suggestion unworthy of his notice, and that he and others who have more leisure and ability than myself, will pursue the investigation, so that our knowledge on this highly interesting and important subject may be perfected.—I am, sir,

Your obedient servant,
JOHN M. CAMPLIN.

11, Finsbury Square,

MEDICO-LEGAL EVIDENCE IN A CASE OF SUSPECTED POISONING.

To the Editor of the Medical Gazette.

SIR,

IN allusion to Mr. Holland's letter and remarks upon the medico-legal evidence in a case of suspected poisoning, I beg to state that there are several important errors and omissions, which quite alter the view of the case, but which I decline remarking upon, as it is Mr. Dyson's intention to address you at his earliest convenience. Mr. Dyson was present at the examination solely at my request, as I knew that he was in the habit of making frequent inspections for the Coroner. There was no expectation of his evidence being required until the result of Mr. Davies' chemical examination was hinted at previous to the third sitting of the adjourned inquest, when it was thought advisable to have his

opinion in conjunction with my own. As soon as it was intimated to Mr. Dyson that his presence would be required, he made notes of the principal points, which notes were produced at the inquest, but not read, as the jury desired him to give his opinion in as few words as possible, and not to enter into particulars.—I am, sir,

Your obedient servant,
JOHN GREGSON HARRISON,
Surgeon.

Manchester, 4, Piccadilly,

CAUSES OF DEATH AFTER OPERATIONS IN THE LONDON HOSPITALS.

To the Editor of the Medical Gazette.

SIR,

As Dr. Chevers seems to deny that his "exposition is principally based on my autopsy-histories," I beg leave to alter the expression. Dr. C. says, "I carefully examined the accounts of all the cases where death occurred from the secondary effects of operations and mechanical injuries of every description which have been entered in the post-mortem registers of the Museum (of Guy's Hospital) during the last fifteen years (from May, 1827)." This date is in a note, which, not observing, I concluded that fourteen years of work, instead of thirteen, out of fifteen, belonged to me and those who have done duty for me. The data which he has deduced from hence seem to be the only facts he furnishes, and as I have been employed performing the inspections, demonstrating the appearances, and recording the histories, from October 1829 till now, with some intermissions as well as with some little perseverance, I hope my hasty little note may be pardoned. Perhaps I may be allowed to say Dr. C.'s exposition is, in some measure, based on my autopsy-histories.

The tabular analysis of some 2000 cases may not be altogether unworthy of notice, if only for example's sake. The plan adopted is to set down: first, the disease or the injury treated; secondly, the organs affected, in the order in which their affections seem to have been important; and thirdly, casual appearances. For examples:

May 1835: Wm. H——, æt. 35, fractured leg, gangrene, hæmorrhage, small kidney, brain, stomach ulcer.

Mary S——: Femoral hernia, bloody peritonitis simulating hæmorrhage (after operation), pericarditis, dissolved œsophagus.

Nathaniel C——: ham aneurism, ligatured, gangrene, diseased kidney.

Wm. T——, æt. 21: amputation, pul-

monary abscesses and emphysema, meningitis, inflamed veins.

The records themselves follow the more common plan: describing, successively, changes in the head, chest, and abdomen, &c. For my own part I have generally avoided all negative statements.—I am, sir,

Your obedient servant,

T. WILKINSON KING.

36, Bedford Square, May 17, 1843.

CIRRHOSIS OF THE LUNG.

DR. STOKES exhibited to the Pathological Society of Dublin a specimen of that disease of the lung, first described by Dr. Corrigan, under the title of cirrhosis of the lung. Its general characters are, a tendency to consolidation or contraction of the pulmonic tissue, with dilatation of the bronchial tubes. Dr. Stokes' patient had been labouring for months under cough, with dyspnoea and hectic fever, and died two days after her admission into the hospital. The physical signs were dulness of sound on percussion over the upper part of both lungs, but no decided or unequivocal signs of cavities. The appearance of the lungs on dissection was very characteristic; the left, which was the more diseased, was greatly diminished in size, and very irregular on its surface, so that when the hand was passed over it numerous small bodies could be felt, conveying to the fingers the impression of tubercles existing on the surface of the organ; this was produced by the presence of air vesicles. On making a longitudinal section of the trachea and primary divisions of the bronchi, the right bronchus, immediately after it branched off from the trachea, became greatly dilated, so as to exceed the latter in diameter, while the left bronchus was evidently contracted and reduced below its ordinary calibre, but dilated again a little further down.

At a subsequent meeting, Dr. Greene exhibited another specimen of pulmonary cirrhosis, with dilated bronchial tubes, closely resembling phthisical cavities, taken from a woman who had long suffered from intractable cough, and who was affected with a train of symptoms closely resembling phthisis. The physical signs were, cavernous respiration and distinct pectoriloquy in the right infra-clavicular space; the latter sign was also found at the inferior angle of the scapula, and in the right axilla: distinct gargouillement, with bronchial respiration, could be heard in various parts of the chest. The left lung presented the signs of bronchitis. The lung, on examination after death, was found to be diminished in size and indurated; the cavities formed by the dilatation of the tubes were of considerable

size, and did not contain purulent matter ; they were largest near the surface of the lung, and towards its upper part. Their cartilaginous structure could be distinctly traced. There was not any sign of tubercular deposition in either lung. The pleura was greatly thickened, and the diaphragm was adherent to the liver.

Laennec attributed this complaint to constant cough and accumulation of mucus in the bronchial tubes. His opinion is, however, liable to objection, and his account of the causes to which the dilatation is owing is not sufficient to explain all the phenomena. According to Dr. Corrigan, the primary seat of the disease is in the web of cellular tissue which constitutes the matrix of the lung, which has a tendency to contract, so as to produce, when the disease is advanced, a very considerable obliteration of the air-cells. He thinks the diminution of the lung the first step in the disease, of which the dilatation of the bronchi is a consequence.—*Dublin Medical Journal.*

NARCOTIC EXTRACTS.

MB. BATTLEY has commenced the preparation of narcotic extracts and liquors at the Laboratory, Moorfields, and will be happy to exhibit and explain his processes to any gentleman who may be disposed to witness them prior to their publication. Mr. Battley attends at the Laboratory daily from 3 to 5.

LUMLEIAN LECTURES

DELIVERED AT THE
COLLEGE OF PHYSICIANS,
MARCH 1843,

BY GEORGE BURROWS, M.D.
Physician to St. Bartholomew's Hospital.

LECTURE III.

*On affections of the brain and spinal cord
depending on acute disease of the heart.*

IN my second lecture I concluded an account of the modifications which the circulation in the brain is capable of undergoing in health and disease; and particularly of the variations in the quantity of blood within the cranium, under the influence of abstraction of blood, of posture, and of obstruction to the return of blood from the brain. I then proceeded to shew that pressure was an important principle both in sustaining and destroying the functions of the brain. From physiological and pathological considerations, I supported the opinion, that a compressing force is continually exerted upon the substance of the brain, and that this pressure is produced by vascular distension. I then considered the effects of variations of this pressure on the healthy brain, suggesting the probability that the effects of increased vascular pressure are often obviated by a transference of the extra-vascular serum to the spinal canal. This led me to support the opinion of Sir Everard Home, that the serum in the cerebral ventricles was the means of diffusing equable pressure throughout the mass of the brain.

I then applied this principle of vascular pressure to explain the phenomena of those affections of the brain which are of an intermitting character, such as epilepsy, although the cerebral lesion is permanent. I also attempted to explain the phenomena of syncope as depending rather upon deficient

vascular pressure than upon insufficient supply of blood to the brain.

Lastly, I adverted to the peculiar nervous symptoms attendant on anæmia, and explained their development on the same principle of deficient vascular pressure on the nervous centres, rather than on the simple condition of anæmia of these parts.

I had proposed to have continued this argument in its application to other cerebral affections, particularly to the different forms of apoplexy; but I am unavoidably compelled to postpone these remarks to a future opportunity.

The subject of this lecture will not, however be foreign to the principle I have been advocating, viz. the influence of the central organ of the circulation on the functions of the brain.

Upon the present occasion I shall invite your attention to a class of cases which are often misunderstood, and where all the symptoms indicate a severe affection of the nervous centres; but which, in reality, depend on disturbance of the circulation produced by active disease in the heart and its membranes.

The diagnosis of diseases of the heart has occupied so much attention during the last twenty years, that it is almost impossible to anticipate any important additions to our knowledge of this part of the history of cardiac affections. But it appears to me that the full extent of the influence of diseases of the heart upon other organs, and especially upon the brain, has not been thoroughly estimated by authors on diseases of these organs, and certainly not by the mass of the profession.

The influence of hypertrophy and valvular diseases of the heart upon the brain, has, indeed, been treated of by numerous writers in the present day, and by none more successfully, in my opinion, than by our late talented and lamented fellow, Dr. Hope. It is not, however, upon these chronic lesions of the heart, which usually afford ample opportunities to the physician to form his

diagnosis, and adopt suitable treatment, that I now wish to offer a few observations: it is particularly in reference to peculiarities attending acute disease of the heart that I venture to claim your attention.

Different systematic writers on diseases of the heart have incidentally mentioned that inflammatory affections of that organ are occasionally accompanied with such severe symptoms of nervous irritation, that the primary affection of the heart is either overlooked altogether, or is so masked by the nervous disorder that it is not detected until irreparable mischief is done to a vital organ. A few cases of the same kind are to be found recorded in periodicals, and in the Transactions of medical societies, during the past twenty years. But a connected view of these remarkable and frightful cases has not, as far as I know, been hitherto presented to the medical public. Without arrogating to myself any merit for originality in the view of them which I am about to offer, I think a synopsis of them will be a suitable illustration of the great pathological principle I have been upholding in these lectures, viz. the influence of modifications of the circulation on the functions of the brain. The earliest recorded case of this kind is that detailed by Mr. Stanley*. Dr. Abercrombie, in 1821, communicated a nearly similar case to the Medico-Chirurgical Society of Edinburgh, in a paper entitled, "Contributions to the Pathology of the Heart." It is singular that this valuable essay from so distinguished a physician should have escaped the notice of (I believe) all subsequent writers on diseases of the heart. Dr. Latham was the next in the order of precedence to call attention to this deceptive form of cardiac inflammation; and he informs us†, "that when he first related the particulars of his case to several medical friends, they looked incredulous, or rather contemptuous, of the man who would mistake an inflammation of the pericardium and heart for an inflammation of the brain." Nevertheless, I shall present to you a short account of many analogous cases, occurring in the practice of men of eminence both in Paris and in London. How many others have occurred in the practice of physicians who have been less candid in recording their mistakes, and how great a number must have happened in the practice of those who were unable, or who took no pains, to distinguish these deceptive cases, it is impossible to say. Andral‡ and Bouillaud§ have recorded cases of this kind, as well as Dr. Copland||, Dr.

Macleod*, Dr. F. Hawkins†, and a few others in this country. But the most interesting and valuable information upon this subject has been given to the profession by Dr. Richard Bright, in his account of "Cases of Spasmodic Disease accompanying Affections of the Pericardium." (Vol. 22, Med. Chir. Trans.)

The late Dr. Hope, in his elaborate Treatise on the Heart, remarks, that those cases of disease of that organ which simulate an affection of the brain are very rare; and it is remarkable that with his unremitting attention to diseases of the heart, he never met with a single instance in his own experience. It has so happened that four or five such anomalous and deceptive cases have come under my observation; and I have reason to believe that they are of more frequent occurrence than is commonly supposed.

Authors on diseases of the brain and spinal cord, have indeed, and especially of late years, pointed out the numerous extraneous sources of irritation capable of inducing symptoms of disordered functions of those nervous centres. Such symptoms have often been mistaken for the effects of morbid changes going forward in those centres; but as far as I have been able to ascertain, these authors have scarcely ever alluded to acute diseases of the heart, as the sources of irritation to the nervous centres.

In Dr. M. Hall's recent volume, "On Diseases of the Nervous System," he devotes a chapter to the consideration of those affections which he terms "of remote origin." The effects on the nervous system from intestinal irritation, from loss of blood, chlorosis, gout, shock, and affections of the kidney, are there carefully pointed out; but he only incidentally alludes to those remarkable disorders of the nervous centres excited by active inflammation of the heart and pericardium.

Having given this concise summary of the scattered information we possess on this interesting point in the history of diseases of the heart, I shall now direct your attention to a series of cases of inflammation of the tissues of that organ, where the disease was altogether mistaken for affections of the brain and spinal cord, or, where the prominent symptoms were referable to those nervous centres. I shall show that there is scarcely an affection of the cerebro-spinal system which may not be simulated by inflammatory diseases of the heart and its membranes.

I shall begin with citing (1) some cases which were marked with all the usual symptoms of inflammation of the brain and its membranes; (2) cases simulating mania and dementia; (3) cases characterised by apo-

† Gulstonian Lectures on Rheumatism.

plectic and epileptic symptoms; (4) cases with well-marked symptoms of tetanus and trismus, and, (5) others, still more numerous, accompanied by symptoms of aggravated chorea and hysteria.

These various cases are collected from different sources, and in adapting them to the object I have in view I have necessarily been obliged to curtail the histories as they stand in the original authors.

CASE I.—Active articular rheumatism, complicated with carditis and pericarditis, presenting the ordinary symptoms of an inflammatory affection of the brain.

In April, 1816, one of the boys at Christ's Hospital was attacked with febrile symptoms, and pain in one thigh and knee. The pain in the limb quickly subsided, when he became restless, sleepless, and delirious. When asked if he suffered pain, he pointed to his forehead. On the third day of his illness he had a kind of convulsive fit, which soon went off. He passed another restless night with delirium, and gradually sank into fatal coma on the fourth day, never having complained of any pain in the chest throughout his illness.

It having been considered, from the general character of the symptoms, that there was inflammation going forward in the brain, all the remedies were directed to that organ; and upon examination of the body the head was first inspected. But after an attentive examination of the brain nothing further could be remarked than that the vessels were generally turgid; not more so, however, than is frequently seen when death has taken place under circumstances that led to no suspicion of affection of the brain. Upon opening the pericardium it was found to contain between four and five ounces of turbid serous fluid, with flakes of coagulable lymph floating in it. The entire free surface of the pericardium, both of the loose and reflected portions, was covered with a thin layer of lymph, exhibiting a reticulated appearance. Upon cutting through the parietes of the heart, the muscular fibres presented an exceedingly dark colour. The fibres were also very soft, and loose in their texture, easily separable, and with facility compressed between the fingers. Upon looking close to the cut surfaces, numerous small collections of dark-coloured pus were visible among the muscular fibres.

The internal lining, valves, and every other part of the organ, exhibited nothing worthy of remark, except a state of general turgescence of the capillary vessels, and that all the cavities of the heart were loaded with coagulated blood.

Upon this interesting case, Mr. Stanley makes the following remarks.* "We here

have presented to our consideration an instance of inflammation attacking the heart, so violent as to pass immediately into supuration, and at the same time so destructive as to prove fatal in four days from its commencement; and yet of the symptoms which arose, there was not one which appeared directly referable to the affected organ; on the contrary, from their general tendency, the attention was diverted from the central organ of the circulation, the actual seat of disease, to the centre of the nervous system, where there existed no organic derangement.

CASE II.—Idiopathic pericarditis giving rise to chorea, and symptoms of an inflammatory affection of the brain.

A young lady, æt. 16, came under Dr. Abercrombie's care on the 8th of January 1812, complaining of acute pain at the pit of the stomach, with very short breathing: pulse generally 130, extreme restlessness, almost no sleep, with a good deal of delirium. In the third week, after antiphlogistic treatment, the pain abated, and she could take a full breath. Afterwards she fell into a state resembling chorea, with convulsive agitations of the limbs, constant motion of the head, wild rolling of the eyes and delirium, which soon increased to such a degree, that for several days she was with difficulty kept in bed. She no longer complained of pain; the breathing was natural; the pulse 120, and small. After this she gradually recovered her usual health, but on the 20th April, upon exposure to cold and fatigue, she was seized as before, but the pain was more towards the left side. It was accompanied with dyspnoea, anxiety, and restlessness. She died on April 26th, with increased dyspnoea, great anxiety, vomiting, and rapid sinking of the vital powers. Upon dissection, a thick layer of soft coagulable lymph was found interposed between the surfaces of the pericardium, which were adherent throughout. There was a deposition of the same kind upon the exterior of the pericardium, in some places nearly half an inch in thickness. The surface of the heart was dark-coloured and very vascular. The lungs were in some places indurated. The other viscera were healthy.

After detailing six other cases of pericarditis terminating fatally in the acute stage, Dr. Abercrombie observes*, "a remarkable circumstance in the history of this dangerous affection is, that it may be going on rapidly, yet insidiously, while our attention is occupied by symptoms which have no relation to it."

* On Carditis. Transactions of Medico-Chirurgical Society, Vol. vii.

* Contributions to the Pathology of the Heart, Transactions of Med. Chir. Soc. of Edinburgh, Vol. i. 1821.

CASES III. AND IV.—*Pericarditis, without any signs of rheumatism, giving rise to symptoms of inflammation of the brain.*

Dr. Latham has recorded* the case of a young woman, which is strongly impressed upon my recollection, who was admitted into St. Bartholomew's Hospital, in 1828, and in whom all the symptoms led to the belief that the brain was inflamed. The whole force of the treatment was therefore directed to that organ. The woman died; and upon dissection the brain and its coverings were found in a perfectly healthy and natural state, and the pericardium, towards which there was no symptom during life to induce the slightest suspicion of disease, exhibited unequivocal marks of acute inflammation.

Another woman, æt. 40, was admitted, in 1839, into St. Bartholomew's Hospital, suffering under slight delirium, fever, and other symptoms of an inflammatory affection of the brain. She was treated for this supposed affection of the brain, and did not present a single symptom referable to the heart. She sank in about four days after admission. No disease was found in the brain or elsewhere, excepting the free surfaces of the pericardium being coated with thick honeycomb lymph, which had evidently been effused within a few days previous to her death.

There appears to have been one peculiarity common to three out of the four cases I have just recited, which was, that, throughout their progress, there was no symptom present which directed attention to the organ affected. In the case recorded by Dr. Abercrombie, the patient had complained of pain in the epigastrium, and of dyspnoea, before the accession of the symptoms of affection of the brain and spinal cord; and these symptoms caused his treatment to be addressed near to the organ affected. Nevertheless, this case, as well as the other three, proved fatal.

CASE IV. —*Rheumatic pericarditis, attended with chorea and symptoms of inflammation of the brain and spinal cord.*

In April 1836, Dr. Richard Bright was summoned to attend a young man, æt. 17, who, twelve days previously, had been attacked with rheumatism. On the sixth day of the disease spasmodic symptoms appeared; and at the time of Dr. Bright's visit he was labouring under symptoms of severe chorea, the spasms being more violent than almost ever seen in that disorder. Although no particular symptom pointed out disease of the heart, still it was rather suspected. In a few days the spasms assumed the character of the most violent convulsions; his speech became indistinct, there was diffi-

culty in opening the mouth, and the mind began to wander. The *delirium* gradually increased until it was absolutely necessary to put him under personal restraint. He died at the end of three weeks. In this case lymph was found effused in abundance on the interior of the pericardium, and, to a slight extent, on the exterior of that membrane. The valves of the left side of the heart were fringed with vegetations. The brain was perfectly healthy*.

CASES VI. AND VII.—*Rheumatic pericarditis detected during life, accompanied with symptoms of inflammation of the brain, and terminating in recovery.*

In Dr. Macleod's essay "On Rheumatism, &c." published in 1842, there are two cases of rheumatic pericarditis recorded, in which symptoms of inflammation of the brain supervened, and which were both successfully treated. The first, a young woman, æt. 27, was admitted in the third week of rheumatic fever into St. George's Hospital. On the following day some incoherence was remarked, and the physical signs of pericarditis detected. On the third day constant delirium supervened, with restlessness and jactitation, so that it was necessary to put on a straight waistcoat. At the expiration of a week the delirium began to subside; and, on examination of the heart, the friction sound had disappeared, but the sounds and impulse of the heart were feeble, distant, and intermittent. She gradually improved during the ensuing ten days, when she was twice affected with a convulsive fit of an epileptic character. From this time she progressively improved.

The treatment of this successful case consisted of bleeding, once generally, and once locally, calomel and opium, with purgatives, and blisters to the chest.

The second case related by Dr. Macleod occurred in a man of intemperate habits, æt. 39, who was admitted, September 1837, into St. George's Hospital, labouring under acute rheumatism of three weeks' duration. He was bled, purged, and took calomel and opium. On the fourth day after his admission he was observed to be incoherent, with much wildness of expression. His mouth was already affected by mercury, and he was therefore ordered a grain of opium every six hours. On the following day the delirium had increased; so that at times he was unmanageable, and he had a fit. The physical signs of pericarditis were now detected. During the five following days the same symptoms persisted, and were treated with repeated doses of the acetate of morphia. From this period the delirium declined, and the friction sound disappeared. He gradually recovered; and after a time the sounds of the heart became natural.

* *MEDICAL GAZETTE*, Vol. iii.

* *Medico-Chirurgical Transactions*, Vol. xxii.

I think we can hardly attribute the success which attended the treatment of these two last-mentioned cases, as compared with the want of success in the five preceding instances, to any other circumstance than the early detection of pericarditis by its physical signs. In these two encouraging cases there does not appear to have been any symptom referable to the heart prior to the occurrence of the delirium, and the physical signs of pericarditis were not detected until after the supervention of the peculiar cerebral symptoms.

In the two following cases of rheumatic pericarditis we shall remark a still further, more serious, and permanent injury done to the brain. In both, indeed, life was preserved, the one however terminating in dementia, the second in insanity.

CASES VIII. AND IX.—Rheumatic pericarditis, accompanied with chorea, and ending in dementia in one case, and in insanity in the other.

A housemaid, æt. 24, was admitted into St. Bartholomew's Hospital, Aug. 23, 1838, under the care of one of my colleagues, suffering from rheumatism, affecting almost every joint of the body, and causing the most acute suffering, together with much fever. On the following day the respiration was observed to be hurried, and accompanied with pain about the præcordia. Auscultation at this time discovered no unnatural sound about the heart. She was bled from the arm; cupping-glasses were applied beneath the scapulae; calomel and antimony administered internally, and then colchicum. At the expiration of a week her pains still continued, and as the colchicum had disturbed the stomach and bowels, it was determined to treat the case with opiates. During the ensuing week her pains declined, not uniformly, but rather remitting; her nights, however, were sleepless. On the 8th of September I was requested to see her. I found her sitting up in bed, moaning and wringing her hands, with a vacant expression of countenance. She did not appear conscious of what was passing around her, or scarcely so; she did not answer questions, or only in monosyllables, and when much urged: she occasionally put her hand to her head when questioned about pain there. During the previous night she had been wakeful, delirious, and constantly getting out of bed. I immediately suspected the nature of the case, and by a careful auscultation was able to detect a *to and fro* friction-sound over the whole præcordial region. She was again depleted twice locally, calomel and opium were administered freely, mercurialunction commenced, and a blister applied over the cardiac region. In spite of these remedies the delirium continued during the ensuing

week, the rubbing sound still being audible; she became purged and exhausted by the mercury, without affection of the gums. Milder mercurials, with opiates, leeches, and a blister to the chest, were now employed, and she was removed to a separate ward on account of her noise disturbing the other patients. Her condition remained, however, nearly the same, being delirious throughout the month of October. In the beginning of November she became more tranquil, and even took some part in the nurse's duties in the ward. She never spoke, unless to answer questions, and then very briefly. She was discharged on November 19, nearly in this condition, having had no return of rheumatism, nor at this time could any unnatural sound of the heart be heard.

On Oct. 25, 1838, a girl, æt. 16, was admitted into the same ward, suffering under rheumatism, which was not very severe. On November 2d she appeared very restless, and kept constantly moving about her arms, but not in that jerking manner commonly observed in chorea; her manner, too, appeared strange, and when addressed she did not answer the questions which were put to her, but spoke of something else, and then after some hesitation. The movements of the arms and legs became in a day or two more violent; she was continually delirious, and it was necessary to employ personal restraint. Her rheumatism disappeared, and I was informed, for I did not see her until a later period, that there was no unnatural sound of the heart.

She continued in this state until Nov. 8, when the chorea gradually subsided, but the strangeness of manner remained up to the time of her discharge, December 3, 1838. She however answered questions more readily, but was harassed by delusions, insisting that she was in Newgate, whither she had been sent for her wickedness.

It was remarkable that this and the former patient, although they never addressed any one, nor spoke to each other, were always to be found together, in whatever part of the ward they might happen to be, where they sat and looked at each other, regardless of anything else.

Although the physical signs of pericarditis were not detected in the last described case, I think that when its history is compared with other similar affections of the nervous system, coming on in the course of rheumatism, there can be little doubt as to the existence of an insidious pericarditis in this patient also.

CASE X.—Pericarditis, attended with symptoms of apoplexy, and general paralysis.

M. Rostan* relates the case of a woman

* Recherches sur Ramollissement du Cerveau.

who was admitted under his care, suffering from general uneasiness. On the second day she was suddenly seized with a complete loss of consciousness; her eyes were fixed, the eyelids open; the cheeks flushed; the pulse at the wrist, and impulse of the heart, scarcely perceptible; the limbs motionless, except when pinched. She remained in this state four days, and died.

The pericardium was found covered with false membranes, and bloody serum effused into its sac. There was no appreciable lesion in the other organs.

CASE XI.—Apoplexy occurring in the course of undetected pericarditis, not rheumatic.

A young man, æt. 21, was admitted (March 1834) under the care of M. Bouillaud, labouring under general dropsy. Twelve days after his admission he was attacked with sudden loss of consciousness; his eyeballs were turned upwards; his breathing became stertorous; his lips covered with frothy saliva; his limbs, instead of being thrown about in convulsive movements, were completely paralysed. On the following day he had two or three similar apoplectic seizures, which however did not last many minutes. He was also observed to be occasionally slightly delirious. On the fifth day after the appearance of these cerebral symptoms the tumultuous action of the heart induced M. Bouillaud to examine the condition of that organ more carefully than he had previously done, when he distinctly ascertained the presence of the physical signs of pericarditis. On the following day the patient died.

Dissection discovered abundant effusion of lymph into the pericardium, with signs of endocarditis in the left ventricle, also recent adhesions with some serous effusion into the right pleura, with extensive consolidation and softening of the right lung. The brain presented no morbid appearances. M. Bouillaud remarks* on this case, that without the assistance of auscultation and percussion it would have been impossible to have detected the pericarditis in this man. He never complained of pain in the region of the heart, and there was no suspicion of rheumatic inflammation in any part of the body. M. Bouillaud flattered himself that this pericarditis had come on in the night previous to his detecting its presence, and that it had been brought on by exposure to cold when the man, in a state of delirium, went to the water-closet. It appears much more probable that the pericardial as well as the pneumonic inflammation had already made considerable progress at the time of the first apoplectic seizure.

CASE XII.—Undetected pericarditis, accompanied with symptoms of inflammation of the spinal cord.

Andral details† the following case of acute pericarditis terminating fatally, where the symptoms were those of inflammation of the spinal cord, delirium and tetanic spasm being especially prominent.

A woman, æt. 26, who had recently miscarried, was brought into La Charité Hospital with so much delirium, that no account of her complaint could be obtained from herself. Her delirium was characterised by a remarkably obstinate taciturnity; her lips were observed to be drawn apart by convulsive twitches. On the following day her head was frequently drawn backwards, and her body thrown up in jerks. She appeared to understand questions, and answered, but was incoherent. On the fourth day after her admission the delirium disappeared. The muscles of the face were constantly convulsed, and her upper limbs every now and then became as rigid as in cases of tetanus. On the fifth day the delirium returned; her limbs were palsied; she fell into a state of coma, and died that evening.

On inspection of the body, the membranes and substance of the brain and spinal cord were found without the slightest morbid change; the surfaces of the pericardium were covered with soft lymph, and several ounces of turbid serum were contained in the sac. There was no disease of any other organ.

M. Andral, in recording this curious case, recommends it to the serious attention of his readers. It appears to him to show, that in consequence of the idiosyncrasies of individuals, the lesion of any important organ may produce, sympathetically, the most varied nervous symptoms, such as are usually the consequence of disease in the nervous centres themselves. Although M. Andral describes delirium as one of the symptoms present in the foregoing case, yet there is no evidence of delirium in the report, beyond the obstinate taciturnity, which may have arisen from the inability to command the organs of articulation.

CASE XIII.—Tetanus in its most aggravated form, occurring in a case of undetected rheumatic pericarditis, which was treated as inflammation of the spinal cord†.

A robust lad, æt. 16, was admitted under the care of M. Bouillaud, in March, 1834. A fortnight previous to his admission he had had swelling of his hands and arms, which prevented him from working. Shortly afterwards he was seized with convulsive con-

* *Traité des Maladies du Cœur*, tom i. p. 319.

* Clin. Méd. t. i. p. 34.

† Bouillaud, op. cit. tom. i. p. 333.

tractions of his fingers, which were regarded and treated as epilepsy.

At the time of his admission his eyes were fixed and haggard, and the pupils dilated. He had the aspect of a man who apprehended some great danger; his intellect was clear, but he replied to questions with a trembling voice, his articulation being interrupted by cries and sobs, called forth by severe cramps in his limbs, and a feeling of suffocation. The fingers, hands, fore-arms, toes, and feet, were violently contracted. The muscles of the lower jaw, of the abdomen and limbs, were as hard as stone during the spasms. The mouth was opened with difficulty. The whole body, but particularly the face and chest, streamed with perspiration, which became more abundant with the return of the cramps.

During the four succeeding days he suffered from repeated attacks of spasmodic contractions of the limbs, with more urgent symptoms of trismus. Any attempt to swallow aggravated his sufferings. During the continuance of these symptoms of tetanus the circulation was frequent, the skin hot or perspiring, the bowels constipated, and some dysuria was present. The disease was regarded as inflammation of the spinal cord, and treated by venesection, and repeated local abstractions of blood along the spine. Opium was administered internally, and a warm bath every day.

The patient died on the tenth day after the first appearance of the spasms in the fingers.

Dissection detected a general increased vascularity of the pericardium, with two ounces of pure creamy greenish pus in that serous sac, and old adhesions in either pleura. The brain and spinal cord, with their membranes, were generally congested. The spinal cord was rather firm, except at the superior enlargement of the cord, where there was a circumscribed spot of softening.

In this case pericarditis was never suspected, and its physical signs were not sought after. They probably would have been more obscure than usual, on account of the absence of fibrinous exudations, and the small quantity of purulent effusion into the pericardium. It is also worthy of remark, that although this case was treated by M. Bouillaud with active depletion, and by large doses of opium, nevertheless there was no alleviation of the symptoms.

CASE XIV.—*Undetected idiopathic pericarditis, attended with symptoms of inflammation of the spinal cord.*

Dr. Macintosh* describes the case of a middle-aged man, who suffered from asthma, sleepless nights, cough, and expectoration, and at the same time from spasmodic con-

tractions of the muscles of the extremities. On examining the chest he was found to have an extraordinary curvature of the spine, and to be chicken-breasted. He was unable to inflate the lungs completely. The action of the heart was tumultuous and irregular, occasionally intermitting. On the two succeeding days he appeared to improve under the treatment adopted, the case being regarded as one of chronic disease of the lungs, with enlargement of the heart. On the third day the oppression about the chest increased; but the chief suffering arose from cramps in his extremities, and occasional spasmodic rigidity of the whole body, which was sometimes bent backwards, and supported by the occiput and heels, in complete opisthotonos. He died suddenly in the course of the following night, the spasms having been so severe that he could hardly be kept in his bed.

On dissection, the brain was found quite healthy. No trace of disease was found in the spinal cord, except one old adhesion of the membranes, and some ossific scales on the surface of the arachnoid. The pericardium was large, and contained a considerable quantity of turbid serum, with a deposition of lymph, adhering in several places to the surface of the heart. The heart itself was large; the valves were sound.

The cases of tetanus which I have now related, coming on in the course of pericarditis, should not remain mere pathological curiosities: they should suggest some useful practical rules in the treatment of that terrible nervous affection. The pathology of tetanus is confessedly obscure: numerous cases of that disease have terminated fatally in the hands of the most able practitioners, when no morbid appearances could be found in the spinal cord and membranes. We are obliged to confess our ignorance of the nature of the morbid action in such cases, and affirm that the spinal cord has suffered from irritation.

Dr. Marshall Hall has applied certain epithets to nervous affections, according as the source of irritation is situated in the brain and spinal cord, or elsewhere. When the source of irritation is within the nervous centres, he terms the affection *centric*; and when it is situated elsewhere *eccentric*. The cases I have cited upon the present occasion are examples of eccentric tetanus, the source of irritation being in the nerves of the heart and diaphragm. Considering how obscure is the pathology, and how difficult the treatment of tetanus, it behoves every one henceforth, in cases of trismus and tetanus, which are not traumatic in their origin, to scrutinize the sounds and action of the heart by auscultation, and to seek for the signs of pericarditis. It is a melancholy reflection, but, I fear, a just one, that num-

* *Practice of Physic*, vol. ii. 4th edition.

bers have perished from these supposed diseases of the spinal cord, when in truth the morbid action has been in the heart, although that has not been detected.

The connection of chorea with inflammation of the pericardium has already been illustrated in the narratives I have just detailed; and I therefore feel disposed to add but few observations on this part of the subject. It is, however, very fully discussed by Dr. R. Bright, in his essay "on spasmodic diseases accompanying affections of the pericardium*." No less than five cases of this complication are there recorded by Dr. Bright, who makes the following remarks on their pathology:—"The instances of the combination and alternation of rheumatism and chorea are very numerous; and though I doubt not in some cases (as supposed by Dr. Copland and others), the coverings of the cerebro-spinal mass may be, and are implicated, yet I believe that the much more frequent cause of chorea, in conjunction with rheumatism, is the inflammation of the pericardium. The irritation probably is communicated thence to the spine, just as the irritation of other parts, as of the bowels, the guns, or the uterus, is communicated, and produces the same diseases."

The series of cases which I have brought before you, I think, fully support the correctness of these opinions.

There only remains one other nervous affection, to which I alluded at the commencement of the lecture, as occasionally produced by active disease of the heart and pericardium: it is hysteria. In Dr. Bright's valuable paper is recorded a remarkable case of chronic disease of the pericardium which was accompanied with hysteria.

From this collection of cases, which I have analysed and detailed on the present occasion, we learn that all those groups of symptoms which indicate the most formidable diseases of the brain and spinal cord may arise from the irritation of the nerves of the heart, without any structural change in the nervous centres themselves.

It would thus appear, to employ the words of Andral, "*qu'en raison des susceptibilités individuelles, il n'est point d'organe dont la lésion ne puisse déterminer les symptômes nerveux les plus variés, de manière à produire sympathiquement les différents états morbides dont on place le siège dans les centres nerveux et leurs dépendances*†."

I may now, in conclusion, venture to offer some remarks on the pathology and treatment of these cases, as a distinct class of nervous affections.

It has been supposed by some pathologists that these cases are only met with in connexion with rheumatism, and particularly where pericarditis is engrafted on rheumatism of the joints; but of the sixteen cases I have narrated, no rheumatic affection could be discovered in six of them. In two or three the pericarditis might be regarded as idiopathic; in the others, it came on in the course of chronic diseases of various kinds.

It has also been affirmed by some writers, that when peculiar nervous symptoms do appear in the course of rheumatism or pericarditis, that such nervous symptoms arise from a metastasis of the morbid action to the membranes of the brain and spinal cord. Without denying the occasional occurrence of such a phenomenon, I can only state, that in not one of the twelve fatal cases I have enumerated could a trace of disease be discovered in the brain or its membranes. In only two of the twelve did the spinal cord and its membranes present any thing remarkable. In the case of tetanus cited from the work of M. Bouillaud, the cord and its membranes were vascular, and there was also one small point in the cord softened. In the case of tetanus quoted from Dr. Macintosh, an old adhesion was discovered in the membranes of the cord, and some small ossific scales on the spinal arachnoid. I have already alluded to the opinions of Dr. Bright on the pathology of some of these spasmodic affections, and the mode in which he supposes the nervous centres to become affected. I fully coincide with the general principle of his explanation.

Dr. Bright reports, that in the cases examined by him, the inflammation was not confined to the interior of the pericardium, but existed also on that part of the external surface of the pericardium, as well as pleura, where the phrenic nerve, in its course or distribution, is to be found. Dr. Bright therefore suggests the explanation, "that the phrenic nerve is the more immediate means of communicating the irritation to the spinal cord."

In the case I have cited from Dr. Abercrombie's Essay, there was found not only a large quantity of lymph within the pericardium, but also a layer of lymph, half an inch in thickness, on the exterior of the pericardium. This additional fact gives support to the explanation offered by Dr. Bright; which also derives further confirmation from some observations of M. Bouillaud on these remarkable cases.

M. Bouillaud, in reviewing the general symptoms of pericarditis, adverts to the extraordinary disturbance of the nervous system in some cases of this disease, and proceeds to analyse the peculiarities which have distinguished them. He finds that such

* Op. cit.

† Clin. Méd. t. i. p. 26.

nervous symptoms have occurred when pericarditis has been complicated with pleurisy, and especially with extensive diaphragmatic pleurisy. This opinion he supports by reference to some of his own cases, as well as to one recorded by Corvisart, where the patient, during life, was attacked with spasms of the muscles of the face, and delirium. After death, besides the pericarditis, there was discovered extensive inflammation of the pleura covering the diaphragm. The celebrated republican, Mirabeau, also died of severe pericarditis complicated with pleurisy. The progress of his complaint was accompanied with the most distressing nervous symptoms, which caused him frequently to appeal to his philosophic friend and physician (Cabanis) to put an end to his agony by large doses of opium.

The explanation of M. Bouillaud of the pathology of these cases of pericarditis with aggravated symptoms of nervous excitement, very closely coincides with that given by Dr. R. Bright. But the details of both fatal and favourable cases of pericarditis complicated with pleurisy, recorded in the work of M. Bouillaud, shew that such cases are not necessarily attended with nervous excitement. I have known several instances of rheumatic pericarditis complicated with pleurisy, where no peculiar nervous symptoms were present; on the other hand, I have seen a few cases of pericarditis, where no pleurisy existed, and which were characterised by these strange nervous phenomena.

On this part of the pathology of the heart the late Dr. Hope made the following remarks: "There is no doubt of the fact that pleurisy, especially diaphragmatic, may produce the violent symptoms in question; it is therefore obvious, that this complication might aggravate the symptoms of pericarditis and raise them to their utmost intensity; but it does not follow that all cases of uncomplicated pericarditis should be exempt from such severe symptoms: nor are they." Dr. Hope adds, that the sardonic expression, and peculiar contortions of the features, attending the worst class of cases of pericarditis, are occasioned by the sympathy subsisting between the respiratory nerves of the face, and those of the heart. An impression is conveyed to the spinal cord through the pneumogastric nerves, and reflected to the face through the portio dura.

It would, therefore, from a more extended review of these cases, seem probable, that, although the spinal irritation may in some cases be excited through the phrenic nerves, the same amount and kind of irritation may be equally conveyed through the pneumogastric nerves. The practical value of this advance in pathology will consist in calling attention to the physical signs of the state

of the heart in all obscure and intractable affections of the brain and spinal cord.

Lastly, I shall briefly allude to the subject of the treatment of these nervous affections appearing in the course of pericarditis.

In all the cases which I have adverted to, where the plan of treatment is recorded, abstraction of blood was resorted to. In some the quantity taken was considerable.

In most of the cases, in conjunction with the abstraction of blood, other remedies, usually termed antiphlogistic, were employed. In a few, in addition to abstraction of blood, opium appears to have been freely given; while in some of those where the pericarditis was detected during life, in addition to the abstraction of blood generally and locally, calomel and opium were administered freely; and mercurial inunction was likewise employed in a few: and of these various modes of treatment, the last was the only successful plan.

Of the fourteen cases I have detailed, four only escaped with their lives; and of these, three were treated on the calomel and opium plan, combined with the abstraction of blood. Of the remaining eleven, treated on the various methods I have specified, ten perished.

CLINICAL LECTURES

ON THE

THEORY & MEDICAL TREATMENT OF INSANITY.

Delivered at St. Luke's Hospital,

May 1st, 3d, and 5th.

BY ALEXANDER JOHN SUTHERLAND.

LECTURE I.

Introduction. Different theories of the nature and seat of insanity. Reasons for considering the seat of the disease to be in the brain. Of disorders of the mental faculties. Of fatuity — incoherence — delusion. Of disorders of emotion. Hallucination — illusion — examples of each. Alterations of the sensitive nerves. Alterations of the motor nerves. General Paralysis. Foville's theory.

GENTLEMEN, — Before we go round the wards of the hospital, and before I show you particular cases illustrative of particular medical treatment, I propose to give you a brief sketch of the nature of insanity, considered not as a metaphysical subtilty, but as a disease of the body.

I am fully aware of the difficulty of the task I have undertaken, and of my inability to perform it: the end I have in view will,

however, be sufficiently answered if I shall have added any thing to your previous knowledge which may hereafter be of practical use to you in your profession.

Insanity is a term which comprehends under it so many conditions of soul and body that it is quite impossible strictly to define what species and difference should constitute it as a genus: on the one hand we find alterations of intellect, affection, passion, and instinct; on the other those of sensation and motion.

Inasmuch as it is the brain which presides over the functions of the mind, sensation, and voluntary motion, I shall consider first how far it is probable that the disease may have its seat in that organ; secondly, the alterations in the nerves, the morbid condition of which ministers to the brain false perceptions; thirdly, the changes in the circulating fluid which either precede or follow the attack; this will lead me, lastly, to speak of alterations of function in other organs which are complicated with insanity, either as causes or effects, inasmuch as faults of secretion and excretion have an important bearing upon our subject, more especially as regards medical treatment.

The writers on the pathology of insanity may be divided into those who treat of it as an idiopathic, and those who consider it a symptomatic affection. Different physicians have often looked upon the disease in different points of view. The question—where is the seat of the disease, is a very different one from another with which it is apt to be confounded—whence did it originate. M. Esquirol, for instance, lays much stress upon the disease taking its origin in the different ganglia, and not always in the brain; but he does not say that it has its resting-place in these ganglia. So M. Guislain, although he considers the brain to be always affected in insanity, does not say that it is always primarily so affected. Again, M. Foville, who is generally placed among the advocates for insanity being an idiopathic disease, does not deny that it is both sympathetic and symptomatic. Setting aside, then, the opinions of those who take the middle, and, as I think, the safer course, there remains for us to consider two opposite theories as to the seat of insanity: the one, that it is always a primary affection of the brain, and that the other viscera are secondarily disordered; the other, that it is always a primary disease of one or other of the viscera, and that the delirium is merely a symptom.

M. Georget may be considered as one of the most active representatives of the first theory, viz. that madness is a primary affection of the brain. This theory appears to me to be in direct contradiction to facts, inasmuch as functional and organic changes

in the kidneys, heart, liver, and uterus, do certainly sometimes precede, and are not always the consequences of, insanity. When we find (as I often have) the kidneys marbled and granulated in our post-mortem examinations, are we to conclude that the disease of the brain produced the Bright's kidney, or rather that the diseased kidney produced those alterations in the blood which effected the first functional disturbance in the brain? If time allowed me, I could bring before you many examples of nephritis, enteritis, hypertrophy of the heart, disorders of the uterus and other viscera, which existed prior to, and which were apparently the physical cause of, the subsequent disturbance in the brain. M. Georget discards (art. Folie: Dict. de Med.), I think, rather too summarily the morbid appearances found in some of the viscera in insanity, when he says, "the heart is rarely diseased, and the kidneys are almost always healthy." Although I should agree with M. Georget, and others, in believing that madness is a disease of the brain, I cannot concur with them in thinking that the *fons et origo mali* is always to be traced to that organ.

We have next to consider the theory of Jacobi, that insanity is a symptom of disease; not a disease in itself, but secondary, depending upon disorders in other viscera. There are others of high authority who share this opinion with Jacobi; the great Pinel, for instance, considered the stomach and intestines to be the seat of the disorder, from which point he thought the evil radiated to the brain. The opinion that melancholy had its fountain-head in the colon is as old as Hippocrates; and Esquirol attributes some importance to the displacement of its transverse arch in cases of this description. Dufour places the seat of the disease in the ganglia; M. Prost in the mucous membrane of the intestines. These opinions are in some measure in accordance with those of Bichat, who endeavours to prove, from the frequent morbid appearances found in the viscera of the thorax and abdomen in cases of insanity, and from other facts, that the brain is not exclusively concerned in all psychical phenomena, but that the emotions may have their origin in other viscera. These theories are extremely plausible; and it is very difficult to answer them, because of the obscurity of the relation which exists between the viscera and the mind. Professor Müller has taught us not to confuse the mental operations with the mental principle, and here seems to lie the origin of the fallacy: the mental principle exists every where throughout the body; the mental operations are confined to the brain. He says*, "in short it is evident that the effects of the

* Baly's Translation, 817, Vol. i.

passions upon the different organs subject to the influence of the brain in no way confirm the hypothesis of the passions, or certain mental faculties, having their seat in any other organ than the brain." If we carry our investigation farther, and appeal to comparative anatomy and physiology, as well as to morbid anatomy, it becomes a matter of high probability that the cortical structure of the brain is chiefly the instrument of mental operations. I think that no one who has had much experience in the post-mortem examinations of the insane, can fail to have been struck with the variations from healthy structure which the grey substance, generally speaking, presents. How different are the convolutions of the brain in recent mania, which are every where injected, and highly developed, and appear almost too large to be contained within the cranium, from the pale and shrunken convolutions of dementia!

Professor Owen has pointed out the importance of observing the different direction, the difference of packing, so to speak, of the convolutions in different species of animals: *e. g.* in herbivorous animals the median fissures which divide the folds of the hemispheres converge from the circumference to the centre; in the carnivora they are parallel, while in the human subject they diverge. When we compare the human brain with the brains of animals, we find, at a certain period of foetal existence, the total absence of convolutions, like the smooth surface of the hemispheres of the rodentia. On the other hand, in the full-developed brain of man, we have additions, not only anteriorly but posteriorly, to those folds which have their analogues in the brains of inferior animals. It would therefore seem (even though we had not the brains of idiots to strengthen the supposition) that the convolutions are mainly concerned in the operations of the higher faculties of the mind; and that if, from their deficiency in man, the soul has not the power of communicating with external nature, the reason lies not in the soul's deficiency; for it remains, notwithstanding hereditary mal-conformations, or the decay of disease, as perfect as when it first came from the hands of the Creator.

Recent physiological investigations would lead us to conjecture that the emotions and instincts have a centre of action distinct from the higher intellectual faculties; that, in fact, all psychical phenomena are not confined to the cerebrum, as was formerly supposed, but that the medulla oblongata is the chief instrument by which emotion is manifested; so that if a physiologist were called upon to draw a diagram of the principal seat of action of mind and emotion, he would represent it, not by the centre of a circle, but by the foci of an ellipse. Some doubt, however, still exists upon this subject:

some hold that the medulla oblongata, Dr. M. Hall and others that the spinal system of the nerves, is the main channel through which instinct and emotion flow.

If the brain, the organ of the mind, be diseased, it is a highly probable, though not a necessary consequence, that the mind itself should become affected. In insanity of intellect, as distinguished from that of emotion, all the faculties of the mind are liable to be disturbed in different cases—some more, some less; those, however, which most commonly suffer are attention and association, which comprise memory and imagination; for memory cannot exist without the former, and the pleasures of imagination appear chiefly to take their rise in the latter (see Diss. Encyc. Brit. i. 368). In idiocy there is of course little or no attention; in dementia it is weakened, or almost obliterated; in mania it is distracted by a thousand ideas, furnished by sensible objects from without, and by the mind from within; in monomania it is rivetted to one predominant idea, while association, so busily at work for evil in the mind of the maniac and monomaniac, grafts its false perceptions upon those ideas most habitual to him prior to his disease.

These disorders in the faculties of the mind are usually expressed by the words fatuity, incoherence, and delusion. Fatuity expresses a state of intellect somewhat analogous to the decay of the mind in old age, which is thus very beautifully described by Locke: "Ideas often die before us, and our minds represent to us those tombs to which we are approaching, where, though the brass and marble remain, yet the inscriptions are effaced by time, and the imaginary moulders away."

Incoherence is unconnected discourse. The incoherence of mania, however, differs from that of dementia: the former is owing to a quick succession of ideas passing through the mind too rapidly for all to find utterance; the latter arises from a defect of memory; words, sometimes whole sentences, are omitted; at other times one word is substituted for another, and the whole conversation becomes disjointed and unintelligible.

Delusion is a permanent idea in the mind which is contrary to sound sense and general opinion. That the idea be contrary to sound sense is not sufficient to constitute delusion; for an uneducated man may infer many things which are contrary to sound sense, as that the sun revolves round the earth; but his opinions are not contrary to the general belief of those in the same rank of life with himself, and therefore are not, strictly speaking, delusions. Nor, on the other hand, is an idea which is contrary to general opinion necessarily a delusive one; for a philosopher before the age in which he lives, who advances theories, with sound conclu-

sions, deduced from true premises which contradict general opinion, stands a very good chance of being considered out of his mind—instances of which must be familiar to every one. Such opinions, then, cannot properly be brought under the head of delusions.

If aberration of intellect is an important feature in cases of insanity, equally so is a diseased state of the sentiments, the affections, and the passions: a change in these is generally the first sign of the coming disorder; and when unsettled, these are commonly the last to be restored to a state of health. Cases of insanity exist in which emotion alone appears to be involved, leaving the intellect untouched: this is the moral insanity of Dr. Prichard. So common is it for that part of our nature to be changed in madness, the operation of which we recognize by the words emotion, sensibility, desire, aversion, and the like, that some men, mistaking effects for causes, have asserted that the essence of insanity consists in a wrong action of the soul, and consider all madmen to be sinners. To this theory Professor Müller answers, that "since the action of any part always induces a change in the organic structure which composes it, it necessarily follows that immoderate exertion of the mind, a continued direction of it to one object consequent on external circumstances or great mental excitement, must react on the organization of the instrument of the mental operations; the wrong direction of the thoughts is not a mental disease, but is merely one of its numerous exciting causes" (Baly's Trans. i. 820). This answer of Müller is not quite satisfactory, for it does not go far enough; because it is not sufficient that there should be a change in the organic structure of a part, for this is produced even by the healthy action of every organ; there must be such a change as to amount to disease before we can recognize it as constituting insanity. One of the most difficult questions which we have to decide is, where does passion end and insanity begin? There are many instances of passion which are unjustly attributed to insanity; and yet who is there who has yet been able to limit their shadowy confines? They approach each other so nearly that the description of the one will often pass for that of the other. Take, for example, Seneca's picture of anger, which would apply equally well to a paroxysm of furor. "*Cætera vitia impellunt animos; ira præcipitat. Cæteris etiamsi resistere contra affectus suos non licet, at certe affectibus ipsis licet stare; hæc non secus quam fulmina procellæque, et si qua alia irrevocabilia sunt, quia non eunt, sed cadunt, vim suam magis ac magis tendit. Alia vitia a ratione, hæc a sanitate dehiscit; alia accessus lenes habent, et incrementa*

fallentia, in iram dejectus animorum est. Nulla itaque res urget magis attonita, et in vires suas prone, et, sive successit, superba, sive frustrata insana."

Some men quote lightly the opinion of Locke. "There is scarce any one that does not observe something that seems odd to him, and is in itself really extravagant, in the opinions, reasonings, and actions of other men," which, he says, proceeds not wholly from self-love, nor from education, but from a sort of madness. (I cannot refrain from quoting the rest of the passage, although it is somewhat long). "I shall be pardoned for calling it by so harsh a name as madness, when it is considered that opposition to reason deserves that name, and is really madness; and there is scarce a man so free from it, but that if he should always, on all occasions, argue or do as in some cases he constantly does, would not be thought fitter for Bedlam than civil conversation. I do not here mean when he is under the power of an unruly passion, but in the steady calm course of his life. That which will yet more apologize for this harsh name and ungrateful imputation on the greater part of mankind is, that inquiring a little by the bye into the nature of madness, I found it spring from the very same root, and to depend on the very same cause, we are here speaking of. This consideration of the thing itself, at a time when I thought not the least on the subject which I am now treating of, suggested it to me. And if this weakness, to which all men are so liable, if this be a taint which so universally infects mankind, the greatest care should be taken to lay it open under its due name, thereby to excite the greater care in its prevention and cure." (Ch. 33). How glad would a criminal be of such an advocate as Locke! It is easy to see how he fell into this train of thought: he had previously framed his celebrated definition, that madness consists in correct reasoning from wrong principles, without considering that some madmen reason very accurately, and others are incapable of reasoning at all; and thus, when he compared the obstinacy with which most men adhere to their opinions, with his definition, he found that either his definition must be false, or that all men must be in some measure mad; and in this dilemma he chose to conclude that the latter was correct. Locke appears to me to have been misled by a partial study of the disease: he seems mostly to have had experience of the reasonings of monomaniacs, to which his definition, and his above remarks upon madness, correctly apply, for the monomaniac is capable of reasoning accurately from false premises, and clings to his imagined sufferings and enjoyments with the greater tenacity, the more that you en-

deavour to convince him that he is labouring under delusion. Aware of the difficulty of drawing nice distinctions between passion and eccentricity on the one hand, and insanity on the other, our law has marked out a broad line which must be passed before a man can be recognised as insane. In order to deprive a man of his civil rights, it is not enough that he should be proved insane; he must be proved to be so far insane as not to be able to manage himself and his affairs; in order to shew that he is irresponsible for his criminal acts, it must be made evident that he was so far insane as not to be capable of distinguishing between right and wrong at the time he committed the crime. The law skillfully avoids the difficulty of measuring the capacity of men's minds; it very wisely does not attempt to determine where passion ends, and insanity begins: to define accurately the boundary between one and the other is the labour of him who would separate with distinct lines the mingling colours of the rainbow, or of Arachne's web.

*In quo diversi niteant quum mille colores,
Transitus ipse tamen spectantia lumina fallit.
Usque ades quod taugit idem est ! tamen ultima
distant.—OVID. MET. VI. 65.*

Interesting as this part of our inquiry is, it would be foreign to my purpose to pursue it on the present occasion; I must refer those who wish to follow out the investigation, to the works of Dr. Prichard and Dr. Conolly, and to Shelford, and Collinson, on the law of lunatics.

I must now draw your attention to those false perceptions which are furnished to the diseased mind, either by the nerves of special sense, or of nerves of sense generally: these occur in two ways; either the function of the nerves themselves is disturbed, and conveys to the mind false impressions of external objects, or the imagination conjures up the morbid perception, and acts upon the judgment through this or that nerve; it is, for instance, either the eye, or the mind's eye, which is disordered: these errors of perception are called hallucinations or illusions; words which have often been misapplied. Hallucination is a creation from within, illusion is a mistake from without: the mirage is an example of an illusion which the thirsty traveller of the desert is taught to correct. Supposed visions are examples of hallucinations; both the one and the other are compatible with perfect sanity: before they can be adduced as proofs of insanity, the condition of the understanding and of the character must be taken into consideration: *e. g.* our Saxon ancestors believed that they were pursued by the fauns, forest-fiends, and white women, which haunted the abodes of their fathers in the wilds of Germany: we call this superstition, not insanity. Visions of imagination also have appeared not only

to Colonel Gardner, but to Lord Herbert of Cherbury: "prophetic warnings," as the author of *Distinguished Northerns* says, "have occurred to young and old; saints and sinners; to Bentley the orthodox, to Oliver Cromwell the fanatic, to Littleton the rake, to Nelson the hero, and to Alexander Stephens the buffoon." Examples analogous to these in kind, but differing in degree, are often met with in cases of aberration of intellect; the nerves of hearing and of sight are most commonly the seat of injury; commands issuing from supernatural voices, warnings from deceased friends, persecutions from ideal enemies, visions of angels or of devils, frequently embarrass the bewildered imagination: the nerves of touch are certainly less commonly found disordered than the rest. In some cases I have seen hallucination of one sense, and illusion of another, existing at the same time. As this is a matter of some importance, I shall give you examples first of hallucinations, and afterwards of illusions.

A lady whom I occasionally visit has been blind for some years, and yet scarcely a day passes without her fancying that she sees either rays of light, bright figures, or soldiers.

J. L., set. 45, was a patient of mine in May 1840: he imagined that he was beset by devils, who poured all kinds of blasphemies and abuse through pipes in the ceiling of his room into his ear: at the time he was speaking to me he fancied an evil spirit was crawling over his shoulder and blowing into his left ear, while in his right ear he heard the consoling admonitions of his guardian angel, which counteracted the ill effects of the other. I ordered him some medicine, and recommended him to go into the country; when he returned he told me that instead of having heard the abuse, swearing, and blasphemies, he had been exposed to while in London, the voices assumed the mild accents of the country people with whom he lived.

Examples of hallucinations of smell are not very uncommon, especially in the case of those who imagine they are suffering the tortures of the condemned; these delusions also often accompany alterations of the nerve of taste. False perceptions of taste, unconnected with a foul tongue, derangement of the stomach and bowels, are rare. A patient whom I attended in February 1839, imagined she had murdered a child; she refused her food because she thought it was the flesh of the victim she had slain, and would not drink because every thing she swallowed tasted she said like human blood. The tongue was not loaded; the bowels were not costive: the false perception therefore must be accounted for either by supposing with M. Esquirol that it was created by the

imagination, or by concluding, with M. Foville, that it was due to disease at the origin of the nerve in the brain, not to its termination in the tongue.

Hallucinations of the nerves of touch are, as I have stated, the most rarely met with: under this head the following instances may be placed.

A young officer whom I visited a year ago imagined that by touching people he had the power of magnetising and attracting them. Another patient whom I visited last week imagined that her head had been cut off, and that it was rolling about the room like a ball. The story of the turned head, so well told by the able author of the "Diary of a Physician," is not mere fiction; I have met with cases very similar to it. One man thought that his head was set on the wrong way (as the poor person who was saved from the guillotine). A patient now in the hospital fancies that all her bones are turned round.

I shall now bring before you, as briefly as I can, examples of illusions or mistakes, derived externally from morbid impressions of the nerves.

I visited Miss E. Y. on the 15th of January, 1842: she was æt. 26, of a nervous temperament; pulse 80, rather weak; tongue clean; skin cool; head hot; bowels costive; urine free; catamenia absent six months; thorax not dull on percussion; sounds and impulse of heart natural; no undue action of the carotids; abdomen not distended with flatus. She had suffered under melancholia six months. The cause of her illness was fright. Countenance anxious; pupils and conjunctivæ natural; complexion clear. From the cessation of the catamenia she imagined herself pregnant. She thought also that she had committed several murders, and that the robins proclaimed her guilt by their red breasts, and all the birds in the garden wore black beaks. The glass of her windows she thought was blood-red; the flakes of snow she said were crosses and crowns of thorns; the carts which passed the house contained the dead bodies of her murdered victims; and she lived in continued dread of being cast into a den of wild beasts for her crimes.

Hydrargyri Chloridi, gr. ii. ; Extracti Colocynth. Comp. gr. viij. alt. noctibus.

February 7th.—She had been improving up to this day, when she was allowed to see one of her relations, which brought back the delusions.

Balneum calidum bis in hebdomadâ.

R. Infusi Sennæ comp. Decocti Aloes comp. aa. f3vi. omni mane. Omittantur pilulæ.

March 5th.—She was much the same.

Omittatur Haustus Infusi Quassiae, &c.

R. Decocti Aloes, comp. f3vi. ; Tincturæ Aloes comp. f3i. ; Tincturæ Hyoscyami, f3ss. ; Aquæ Cinnamomi f3vss. omni mane. Repetatur Balneum.

18th.—She was very melancholy and desponding, and thought she was to be burnt or hung; pulse 88, stronger; tongue clean; bowels open; catamenia still absent.

Hirudines vi. regioni pubicæ.

19th.—Better.

Omittatur Haustus.

R. Extracti Colocynth. comp. gr. x. pro re natâ. Repetatur Balneum.

April 8th.—Very much improved. She had written two letters to her friends, and seen her brother. She bore the interview well.

Perstet in usu Balnei.

14th.—The catamenia appeared on the previous evening for the first time since her illness, immediately after she came out of the bath.

20th.—She returned home cured.

I met with a curious illusion of smell in an old sportsman, for whom I prescribed the compound galbanum pill, as he was labouring under insanity with hypochondriasis: he thought from the smell of the assafoetida that I had metamorphosed him into a fox, and that he was to be turned out next morning before the hounds.

It is remarkable to listen to the misconstructions a patient places on the plainest and most harmless expressions, and sometimes the most familiar sounds. An Irishwoman who was in the hospital some little time ago stopped the clock because she thought it was calling her names.

Monsieur U. a patient of mine in 1840, became insane after reading the trial of Madame Laffarge: he fancied that every one about him intended to poison him, and was constantly searching the house, and breaking open drawers, in expectation of finding arsenic: he even imagined that the washerwoman had inserted poison into his linen, and he took his shirt to a chemist to be analysed; the day that I visited him he had been reading the account of the arrival of Napoleon's remains at Cherbourg. He imagined at one time that the spirit of Bonaparte had been infused into his body, at another that it was all-powerful, and was about to work changes in the whole world. Napoleon's figure continually haunted him; he saw it in the sun by day, and in the moon by night. One of his fancies was, that England was to be turned into a large British Museum, and the inhabitants placed

herein as curiosities. He threatened to kill his wife because he was afraid she would be hanged into something ridiculous.

This patient very soon recovered. The treatment consisted chiefly in the use of colchicum with the sesquicarbonate of soda, which was prescribed, as well for its sedative influence, as to correct the dyspeptic symptoms bordering on gout which were present : we took also the following purgative.

R Inf. Gentianæ comp. f3vi. ; Infusi Sennæ comp. f3ss. ; Sp. Ammoniac Aromat. Tinct. Hyoscyami, aa. f3i. ; Magnesiae Sulphatis, ʒiij.

That which makes a strong impression on the mind sometimes serves as the nucleus of the future delusion. A gentleman who was subsequently placed under my care, and who had suffered from a *coup de soleil* but a short time previously, on the first evening of his arrival at Constantinople, as he walked on the terrace of a house opposite the Seraglio, mistook the rays of the moon, which played upon the waters of the Bosphorus, for a direct intimation from heaven that he was the Saviour of the world.

I need not multiply these cases ; you will easily be able to supply for yourselves examples of the same kind. I pass on to false notions furnished to the mind by sensibility generally.

A young lady to whom I prescribed the potassio-tartrate of antimony to relieve the furor which accompanied her disease, had some remarkable delusions brought on by the effect of the medicine. She fancied she was on board-ship ; she sang sea songs, and rolled her body about as if she were walking the deck in a heavy gale ; sometimes she would imagine that she was wrecked, and when the sofa cushions were on the floor, would snatch them up, thinking she was saving her fellow-passengers from drowning.

The remedy, though it certainly caused these delusions, and made her friends anxious lest the disease might thereby be increased, yet by being steadily persevered in subdued the bodily symptoms, and was, humanly speaking, the means of her restoration to health.

Mrs. J. was a patient of mine in 1841 : when æt. 18 she had an attack of erysipelas of the head with delirium. The catamenia appeared when she was 12 years old. She suffered much during the early part of her life from menorrhagia and dysmenorrhœa. She had had two attacks of puerperal mania ; When I saw her she complained of "bearing down," with pain and discharge of matter from the uterus : this gave rise to the illusion that she was in the habit of committing unnatural crimes ; and she imagined she brought forth monsters. She had been treated for ovarian dropsy. I found the ab-

domen resonant on percussion, when she was in a recumbent posture : it was much distended with flatus, hard, and somewhat painful on pressure : in fact she was suffering from dysentery, not from ovarian dropsy, and when I examined the evacuations I found scybala and hardened feces, which she had mistaken for leeches and a litter of puppies. I took the precaution to measure the size of the swollen abdomen, and as the disease yielded to the remedies commonly employed in cases of dysentery, and the swelling was proved by the tape gradually to diminish, she at first began to doubt the reality of her strange fancies, and afterwards completely mastered them.

I shall make no apology for giving you so many examples of altered perceptions, because it is a matter of the utmost importance in practice : if you set them down as the mere effects of imagination, and do not stop to inquire whence they arise, and what is the probable cause of their existence, you will undoubtedly treat the disease very badly ; and your attention may at last be called to the symptom when medicine is of no avail. Patients either with or without the sensation of pain about the præcordia imagine that they are possessed with devils, or have live animals in their stomach : I recommend you never to overlook such symptoms. Some madmen eat their food voraciously, and without even attempting to masticate it. A patient in St. Luke's, who was in the habit of doing this, had had a severe fall on the back of his neck : his friends said he never knew when he had had enough to eat : it is not impossible that the eighth pair of nerves might have been injured by the fall. There are those who eat their own flesh, and other matter which I need not mention here : this is always a very bad symptom. There are others who refuse food, and it has been too often the habit to order them to be fed with the stomach-pump, without taking into consideration the state of the bodily symptoms. I am confident that the majority of patients who refuse to eat do so because there is irritation of the stomach and primæ viæ : if you order an emetic or a purgative you will generally find this symptom disappear. Esquirol never saw any dangerous consequences ensue in mania from obstinate refusal of food : in monomania, however, the case is otherwise : patients who have tried every other means in vain to destroy themselves, will sometimes endeavour to starve themselves to death, and all our art is called into requisition to avoid such a catastrophe.

The capability of the insane to bear the extremities of heat and cold, and go without sleep, has, I think, been overstated. It is very true that some patients expose themselves to the rays of the sun, and go almost naked in the coldest weather, with impunity,

and this is certainly due in some instances to the explanation given by Dr. Watson, viz : " that in abstraction of mind impressions which are unheeded are unfelt and inoperative : " but this in insanity is not only the result of a mental operation ; it is due also to the benumbing effect of the disease upon sensibility generally.

These patients are exactly in an opposite condition to those labouring under maniacal furor, when the least stimulus of light upon the optic nerve, the smallest sound, or the faintest smell, produce or prolong their paroxysm ; but if you think that it is of no practical importance to protect your patients against the severities of frost, or the rays of the summer's sun, you will presently find them suffering, on the one hand, from mortification of the feet, and on the other, from repeated exacerbations of furor, which too probably will end in dementia : and if you do not take proper precaution that your patient be soothed by refreshing sleep, the exhaustion subsequent to his long watchfulness will be a great hindrance to his recovery.

Alterations of motion.—The motive power of the nerves is either increased or diminished in intensity. It is increased sometimes in a surprising degree during the paroxysm of furor, and in that rare disease catalepsy ; cases of which seldom occur without disorder of intellect. To this head should be referred the inclination and power which some patients possess of taking an immoderate quantity of exercise without fatigue : it must be borne in mind, however, that this is by no means common, and that the physical power of the insane should never be overstrained. I have seen some rare cases where the patient would turn neither to the right hand nor to the left, but was impelled by an irresistible impulse to run straight on till he could go no farther, prevented either by exhaustion, or some obstacle which obstructed his course. One of these cases was a young lady, now under my care, whose insanity was manifested, in the first instance, by her getting out of bed in her night-dress, and going in a direct line over hedges, or any thing which came in her way, till she was at length with difficulty extricated from a pond. A female patient, when first admitted into St. Luke's, would get off her chair, and walk round two or three times in a circle, the left side being always turned towards the centre. These cases are interesting, when we reflect that similar results followed the removal of the corpora striata, and lesion to the medulla oblongata, in M. Majendie's experiments. M. Foville has given an account of an interesting case of a woman attacked with intermittent insanity, *who, during the paroxysm, was affected with a remarkable action of the left arm.*

The fore-arm, half flexed, was struck constantly against the body, while the hand remained pendant. She was seized some time afterwards with cerebral hæmorrhage, when the left arm, formerly convulsed, now became paralytic. I have a case under my care at the present time analogous to it. The patient is a gentleman who, about two years ago, received a violent blow on the side of his head while hunting, and became insane soon after. When the paroxysm comes on, he rubs the left hand violently against the right, or upon the left leg, and shudders, while the paroxysm lasts, as if struck with an electric shock. These attacks have come on more frequently lately ; in the beginning of last year they succeeded each other once a month ; they now show themselves about once in every ten days.

Whenever the motor nerves are involved in insanity it is always a bad sign. M. Esquirol has, indeed, said that the complication of insanity with lesions of motion resists all means of cure, and he holds out no hope of long life to the patient. This talented physician has also said that epilepsy complicated with mental alienation is never cured. With all deference to these opinions, still I must say that I have found that it makes an essential difference if the lesion of motion has preceded, not followed, insanity. I have seen insane patients completely recover who have been epileptic, provided the fits came on first, the madness afterwards. I attended a gentleman in 1840, who had suffered from paraplegia, which came on some time prior to the attack of insanity : this case was condemned as hopeless because of the lesion of motion, and because he had many of the wild fancies, and high ideas, which often accompany general paralysis ; yet this gentleman perfectly recovered from his insanity. This and other parallel cases have led me to think this an important distinction to draw.

Ptosis of the eyelid, and strabismus, are bad symptoms, more especially if either is permanent. Asynchronous action of the pupil, dilatation of one iris, and contraction of the other, are also bad signs ; but if the sphincters be involved the patient is not likely to recover, and if the muscles of deglutition participate in the mischief, the case is hopeless. We see from this the importance of attending to the functions of the afferent and efferent nerves in making our prognosis.

Subsequent experience has verified the opinion of Esquirol of the incurability of general paralysis ; as a proof of the justness of this opinion, patients affected with it are not admissible into either Bethlem or St. Luke's, which are hospitals for the admission of those patients only who are deemed curable. You will, perhaps, in one case in

a thousand, find an exception to this rule, and you will meet with, here and there, a patient who may recover, and remain well for a short time, and then relapse. I by no means think that medicine is of no avail in these cases; I believe that some of the symptoms may be materially relieved by it. If you master this subject of general paralysis, you will gain great credit for acuteness of diagnosis. The ear once accustomed to the speech of those suffering under this form of madness is rarely deceived. The first sentence the patient utters will enable you to detect the disease. The sense of hearing is a valuable addition to our diagnosis in diseases of the lungs and heart; it is no less so in general paralysis: there is a thickness, a hesitation in speaking, which sometimes amounts to stammering; it is somewhat like what is termed "clipping the King's English," in drunkenness. Patients have a difficulty in pronouncing the letter R; if you make them say the word February they will generally fail. I have observed frequently a tremor of the upper lip when no tremor of the muscles existed in other parts of the body. The general tremor, however, of every muscle is very marked when it is present. "Tremor occupat artus" was the forcible expression of a patient of mine first seized with general paralysis, and whose case was mistaken for delirium tremens: the peculiar stammering and hesitation of speech was so marked that I did not doubt for a moment that he was paralytic, and pronounced him incurable, although he was able to repeat long passages from Virgil. My prognosis, I recollect, was considered a rash one at the time, but the patient died within a month, having passed through all the stages of the complaint in its worst form. M. Foville says with truth that it is not the power so much as the precision of the voluntary motions which is lost. If a patient, for instance, attempts to write, he will scarcely be able to hold his pen; or if he walks, there is an irregular gait, he will frequently lean over to the left side, and drag one of his legs. One very characteristic distinction between this disease and common paralysis is, that you cannot produce reflex action, because the paralysis is incomplete. The nerves of sensation are deadened, and very sluggishly conduct their oscillations to the brain. M. Foville was the first to take notice of two distinct periods in this species of paralysis. In the first, the movements, although uncertain, have still some degree of vigour, rather, he says, a kind of rigidity, which gives place to a relaxation which goes on increasing more and more. The last stage of the complaint is accompanied by sloughing sores on the sacrum, incontinence of urine and feces, death by coma, convulsions, or epilepsy.

808.—XXXII.

The delusions which accompany general paralysis are very frequently those of very great magnificence. These patients will tell you that they have millions of money; that they intend to pay off the national debt; indeed every thing they touch appears turned to gold. They also often fancy themselves happier and stronger than they ever were before. It is accurately stated that these fancies are not always found; indeed, I visited a gentleman last September who had all the bodily symptoms of this disorder, but who laboured under no delusion whatever, and his natural affections were not perverted. These unhappy patients enjoy but a short period of their elysium of happiness; a change soon takes place, the faculties of the mind fail, the imagination has no longer strength to furnish matter for delusion, and a hopeless fatuity succeeds.

Inasmuch as half the insane labour under general paralysis, it is a subject which has naturally occupied much of the attention of recent writers on the subject of insanity.

M. Esquirol, who, in 1805, first directed the attention of the profession to this subject, says that it is often a symptom of chronic inflammation of the meninges. M. Calmeil, in his work on the Paralysis of the Insane, considers that it is an affection due to disease of the cortical substance. M. Foville believes it to depend upon alteration of the fibrous structure. I find his theory generally quoted as shewing that there are adhesions of the fibres to each other; whereas he says that these adhesions are between the planes, which are easily separated in a healthy brain, but cannot be in many of those of the insane; every effort you make to do so only tears them. It is between the plane of the corpus callosum and that of the hemisphere that this morbid adhesion shews itself most frequently. In the brains of those affected with general paralysis which he had examined during the three preceding years, he had observed twice only the absence of these adhesions between the planes, and in these two exceptions the cerebral nerves, the pons and medulla oblongata, were excessively hard. Speaking of the adhesion of the fibres, he says, "It is very difficult, not to say impossible, to separate them; it appears, if we may be allowed the conjecture, that each cerebral fibre has contracted a morbid adherence to its neighbouring fibre in such a manner as to render their separation impossible." This conjecture, so seductive to the physiologist, one cannot forbear wishing to be true. I believe, however, that it will not be found to be correct, or certainly not to hold good in all cases, for I have seen, under the microscope, the primitive fibres separating from each other, and curling themselves up like the main-spring of a watch; being, in fact, quite as disunited

in general paralysis as in health. If the adhesion of the fibres were the cause of the paralysis, no hope would remain of alleviating the symptoms, much less of curing the patient, whereas I have seen some cases much benefitted by treatment, and there are one or two cases on record where a permanent cure has been made. Whatever be the cause of general paralysis, it must be such as to operate on the whole body, not on any particular part. The alteration in speech is most generally the first symptom, and this would lead us to inquire particularly into the appearances which the medulla oblongata presents. A very frequent cause of the complaint is venereal excess; and this would also direct our attention to the posterior region of the same part. I recollect a case which was at first mistaken for one of general paralysis because the speech was inarticulate, and the movements of the tongue were impaired. It was, however, found on inquiry, that this patient had, a day or two previously, attempted to hang himself: he was cut down, and with difficulty saved: doubtless the medulla oblongata was injured in this case, and the nerve of the tongue paralysed. My colleague, Mr. Luke, had a patient under his care who was admitted into the London Hospital on the 25th of Dec. 1838; he had lost his speech, and never recovered it up to the time of his death, which happened on Nov. 9th, 1839. The brain was examined, and was found healthy, but at the origin of the ninth nerve was found a cyst, which pressed upon it just before it emerged from the anterior condyloid foramen: these are examples of local injury without general paralysis, and they must be carefully distinguished from it. But other examples might be adduced where the brain is first affected, and the medulla secondarily. For instance, the effects produced by alcohol and cold, which, although evanescent, are no less instructive as pointing to the part where the disease may take its rise. Professor Bouillaud has published some cases which have led him to conclude that the faculty of speech is under the guidance of the anterior lobes of each hemisphere. M. Andral says, "What our researches on this subject have led us to conclude is as follows: out of 37 cases observed by ourselves, or by others, relative to hæmorrhages, or other lesions, in which the morbid change resided in one of the anterior lobes, or in both, speech was abolished 21 times, and retained 16 times.

On the other hand, we have collected 14 cases where the speech was abolished without any alteration in the anterior lobes. Of these 14 cases, 7 were connected with diseases of the middle lobes, and 7 with diseases of the posterior lobes." (Andral, Clin.) *Although, therefore, we cannot conclude that the anterior lobes preside over the faculty of*

speech, and although the present state of science does not allow us to point out any special part of the brain which directs it, yet from cases of apoplexy where loss of speech is the only symptom present, we should be led to expect that there are fibres expressly appropriated to its function. From the above facts it appears that embarrassment of speech may arise from local disease affecting the medulla oblongata, and from lesion of the substance of the brain.

Morbid alterations of the same parts are found in general paralysis, but they differ from the appearances found after death in paralysis from apoplexy, in that there is no disintegration of the fibres. We often find, for instance, the medulla oblongata much injected; effusion of fluid in the subarachnoid cellular tissue and in the ventricles; the pia mater thickened; the substance of the brain infiltrated, sometimes soft, sometimes tough and elastic, with the fibres well marked, as if the brain had been for some time steeped in alcohol. I do not think that it has been satisfactorily proved that the disease always commences in the brain and spreads itself to the spinal marrow; I believe that it sometimes commences in the medulla oblongata and radiates to the hemispheres. A patient of my colleague, Dr. Philp, was admitted into the hospital Oct. 28th, 1842. He received a blow on the nape of the neck at the last Bath election, and became insane soon afterwards. His habits were completely changed; he became a drunkard, having previously been a person of temperate habits. Soon afterwards his speech became thick and hesitating, and he was unconscious of the calls of nature. At 1 o'clock, P.M. Dec. 20th, he was seized with apoplexy, followed by convulsions, which occurred every ten minutes, and died at 9 P.M.

In speaking of the post-mortem appearances I shall confine myself to those of the fibrous structure and medulla oblongata. The medullary structure was firm, its fibres well seen. Its cut surface presented many bleeding points. The posterior lobes of the hemispheres of the cerebrum were greatly injected; an effusion of blood had taken place into the arachnoid from each posterior lobe; the blood was fluid, and rested on the tentorium; it had probably been exhaled through the membrane, and would have been converted into a false membrane had the patient lived. No ruptured vessel was discovered. The ventricles of the brain were very large, each containing an ounce of fluid. The medulla oblongata was much injected, and was small, having a pinched appearance, caused by the sliding forwards of the atlas upon the dentata. As this was exactly the place where the man received the blow, it was probably the effect of it; and it is not

Impossible that the depraved desire for drink might have been caused, in the first instance, by the irritation of the pneumo-gastric nerve: however, be this as it may, the disease appears to have originated in the medulla in consequence of the blow. Again, I think that it is highly probable that the medulla oblongata may be first attacked in cases of general paralysis caused by venereal excess. Upon opening the spinal canal of a paralytic patient who died of secondary syphilis, I found the veins so loaded as completely to prevent my seeing the cord. The effect of this congestion is, we know, pressure, and its result is effusion, which will also be a cause of embarrassment to the fibres in this region.

The morbid appearances found in the brain are, however, more frequent than those in the medulla, in cases of this description, and are such as to justify us in appealing to other causes than the adhesion of the fibres, for the production of the disease. Speaking of general paralysis, M. Andral says that "he doubts not that sanguineous congestions contribute, oftener than is supposed, to produce those lesions of motion and sensation, congestions the traces of which disappear sometimes at the moment of death, but whose existence is here so much the more probable, as the entire nervous centre is the seat of greater excitation, and of a more considerable afflux of the fluids." (Clin. Med.)

Nor do I think that the effusion into the ventricles, found often in so great a quantity, is to be disregarded as a cause of the uncertain movements of these patients, since it makes its way by the calamus scriptorius to the spinal canal; and any increase to the fluid there present is, according to Majendie, attended with evil results.

Lastly, the infiltration of the medullary structure is due probably to atrophy of the fibres, just as we see atrophy of the cortical structure followed by effusion. The fibres have, indeed, retained their power of conveying the notices from the sensorium, but their excitability is more or less exhausted, and their vigour gone.

Upon the whole, I believe that there are many structural lesions, and not one only, which exist as causes of general paralysis; such lesions either directly affecting the medulla oblongata, or indirectly affecting it through the brain.

RUDIMENTARY CONSIDERATIONS ON THE NATURE OF IRRITATION.

By T. WILKINSON KING.

(For the London Medical Gazette.)

Definition; rubbing; morbid, flea-bite, local achne; secretory, catarrh; nutritive; absorbent; nervous, pain, scald, extravasation; sympathetic pains; worms; states of the tongue, nares, skin, and anus; teething, epulis; cough; epigastric blow; shock; cerebral irritation; vomit; excito-motory; spinal, hysteric, renal, &c.

CONSIDERING the expressions of writers, and the import of many facts, irritation may, we think, be safely and advantageously defined thus:—A cause of functional disturbance, or a disturbed process, in the animal economy. So far, we shall probably find satisfactory grounds, or at least here seems a clear starting point. We shall not seek to conform to the current attempts to explain irritation, but rather endeavour to pursue a more even and less uncertain course than some distinguished writers have done.

Sir A. Cooper expressed his views thus:—"Numerous examples of sympathetic actions may be adduced; the communication which exists between the uterus and breast is a striking instance of it." To us, the secretion of milk on the contraction of the uterus seems very little more than a physical, or rather humoral, consequence; and all the other correlations of the generative organs, in either sex and in animals, may at least partake of humoral agencies.

Sir A. Cooper next recites examples of natural excito-motory sympathies. "But," he continues, "sympathetic action is also the result of injury and disease, becoming the cause of restoration, on the one hand, or of destruction on the other; and this state of the body I call irritation. Irritation, gentlemen, may be defined to be an altered action excited in the system by an unnatural impression: e.g. the passage of an urinary calculus through the ureter occasions retraction of the testicle and pain in the thigh." It may happen that the obstructed and distended ureter acts

directly on the track of the motor and sensitive nerves which are here concerned. Pain in the loins from disease of the testis seems rather like some bowel-pains referred to the wrong part through inexperience; as the toes seem pained after amputation, and there are various deep sensations that we never learn to localise accurately.

Testitis from gonorrhœa is of doubtful explanation. Continuous inflammation, or mechanical obstruction, are but common consequences. (See Sir A. Cooper's Lectures, page 10.)

We shall find that there is a great variety of irritations—simple, complex, or general; and these all may be modified by the constitution or condition of the individual subjected to any particular cause of disturbance.

Our method of reviewing these varieties will be to bring them forward in the order in which they seem to illustrate each other, rather than that of a rigorous classification, which our present knowledge will ill admit of, and which the study does not require: our plan, however, may finally facilitate a more complete and satisfactory arrangement; for we shall still endeavour to establish the basis of a natural arrangement of the phenomena of irritation.

When the back of the hand is moderately pressed or rubbed, or exposed to heat or cold, or affected by rubefacients, the result is an increase of capillary injection with reparative nutrition; and such an experiment is the basis of one definition of local simple irritation; by which we may infer here an unexplained deterioration of tissue, which is necessarily transitory in a sound body; for the consequent increased afflux of blood speedily restores the health and strength of the capillaries, and they resume their due proportions. The consequences of irritation are widely different under circumstances of disordered health, as we shall hereafter find. The above facts refer to capillary irritation in particular; and we may suppose the case to be devoid of pain, or one where no nerves are discoverable, as in the cerebrum. According to the preceding view, the simple adhesion of an incised wound, the suppuration of the same, the cicatrizing of an ulcer, sloughing, the ulcerative detachment of a slough, and the exuberance of granulations, are

very little more than so many distinct grades of capillary irritation or disturbed process, which depend first, on the kind and degree of mischief inflicted; and secondly, on the state of the materials of repair, of which the blood is the chief.

Observing a flea-bite, the puncture of a needle, or particularly the gentle wound for vaccination, a blush of redness is found to surround the injured point to a considerable extent; making its appearance soon, and gradually and shortly subsiding. This we regard as more resembling a sympathetic action than many instances commonly adduced as such. The sting of an insect produces more disorder, and the poison of the viper still more. We do not know that the more or less extensive horripilation on the application of cold to the hand is not attended with some such sympathetic capillary contraction. It is most experienced by the feebly nourished, the delicate and sensitive.

We have thought that the sudden call to micturition in such a case may be owing to the inward determination of blood causing abdominal tension. Local cold also acts on the blood and its functions universally, and we would not here exclude the idea of nervous influence.

Some regard irritation as always morbid; and this view of the subject, or rather mode of defining the term, is natural enough for those exclusively engaged in the treatment of diseases; but their position is a false one unless a physiological process of simple irritation and reparation be admitted as a basis principle.

Simple irritation, as by great heat, may be widely diffused, but it is not universal, nor even general; indeed, the idea of general or constitutional irritation is extremely complicated, and we do not propose to ourselves to do much more than explore the subject, and to show how far facts support the opinions we hold; how far we conceive the irritation to be falsely interpreted, and how we may anticipate a safer and more hopeful train of study.

Local irritation may be set up in any part of the living body. The capillaries, the nerves, the blood itself, and in short every vital organ or tissue. It is true this may be a novel mode of unfolding the matter, but we trust that a little

patient attention will justify the course we take. It is to be regretted that our progress is surrounded by error as well as difficulty.

We may find a good illustration of local irritation in the circumstances of an inflamed cutaneous follicle. In-spissated secretion obstructs the orifice, or the decline of secretion allows the opening to contract, and the sudden increase of secretion from general causes produces or constitutes the irritation. A little effort re-opens the orifice, or a pustule is formed.

We shall perceive many varieties in the course and consequences of this one simple irritation (obstruction), all of which may assist to explain the state of the constitution in particular cases. Very slowly increasing distension gives rise to a large sebaceous cyst, but when inflammation is suddenly set up around, we cannot avoid the conclusion that the action is determined by the general state of the system, both as to its origin, kind, and course.

Ten or twenty pustules of *acné* may commence at once in consequence of exhaustion, excess, or exposure, and with a purgative, or a warm day, they may all, or nearly all, subside in twenty-four hours. Sometimes the suppurative action is rapid and confined, and the repair as speedy, or, in a similar case, we may conceive that an acute process increases the contents of the cells and their fluidity, and they are ejected without suppuration. With the renewal of the excretory aperture the inflammation disappears. This seems happier, but scarcely so natural as the mere resolute change we have before adverted too. Occasionally the inflammation is much more chronic, often variable, and finally either suppurative or resolute. It may be limited or diffused, attended with different degrees of hardness and tumefaction; sometimes with sloughing or excessive suppuration, especially in the so-called strumous. The tendency to heal, to ulcerate, or form unhealthy crusts, are so many additional and distinct indications of the particular diathesis.

Let us now regard the capillaries under other circumstances of irritation or disturbance.

Secretory irritation.—All the secretory glands of the body may be supposed to act with gentleness or force according as the blood abounds little or much with the peculiar matters

which they are destined to eliminate. Diuretic medicines or urinary salts may irritate the kidney; the matters are excreted, and the organ returns to its original state of quiescence; but habitual potations of gin, or the suppression of other excretions, as that of the skin, causes such a degree of renal irritation, that the organ, after becoming hypertrophic, becomes actually diseased.

We may assume that similar processes of irritation occasionally affect all the secretory apparatuses of the body. Thus cold and catarrh (of any mucous surface whatsoever) are in a manner justly synonymous. Probably the direct application of keen air is a cause of irritative deterioration of the conjunctiva or larynx.

In the general effects of cold to the surface of the body, we see a double cause of what is called reaction, namely, the weakness of the superficial capillaries, whose circulation has been impeded, and the stimulus of matters accumulated in the system by the suppressed secretion. And this is not all; for it is one manifest effect of external cold to retard all functions (chemical, vegetable, or animal), and subsequently, warmth both facilitates and stimulates reaction.

Chronic catarrhs (variable or recurrent) involve hypertrophy of the secreting glands, just as the skin becomes thickened by attritions; and in this way deafness, asthma, and prostatic stricture, may have the same cause and the same course, and may demand the same method of treatment, as constituting forms of local secernent irritation.

Nutritive irritation.—Non-secreting organs become the seat of irritation in a different way. The muscle of the arm, the heart, or the bladder, thickens by increased exertion, unless its nutrition fails; the hand by toil; the lung or brain, by free use, probably endures an irritation which may become excessive, and which, with deteriorated nutrition, involves absolute disease.

We have seen that hypernutrition of a gland may attend or result from secernent irritation; yet there is still another distinct mode or kind of nutritive irritation. The growth of the parts of the body seems to be attended with a state of feebleness, or at least of great vascularity, softness, and susceptibility to disturbance and active

changes; and it is likewise accompanied with a superabundance in the blood of the various nutritive materials. In another place we have dilated on the particulars of different kinds of ossific irritation;—excited nutrition, and bone deposited on bone, according to the prevalence of bone in the blood; and various irritations attended with absorption of bone, as by pressure; or defective deposition of bone from the paucity of the earth in the system. See the article Fracture, in the Cyclopædia of Surgery.)

If it be true that parts are deteriorated in proportion to the degree in which they are used or exerted, and repaired in the same ratio, that is, so long as the blood is freely formed, we may make some further inferences relating to the uses of exercise, by which blood is consumed or altered, and materials for excretion—the stimuli of the excretories—are also made abundant. Even the fluids which aid digestion seem to be more amply produced under these circumstances; and it seems that equalization and freedom of all the functions (with good nutrition) may thus lead to the exaltation of all;—assimilation, circulation, perfective or maturative assimilation, nutrition, and secretion. (See First General Laws or Fundamental Doctrines of Medicine and Surgery, by T. W. King. London, 1840.)

Nutritive irritation does not depend alone on excitement of the organ which grows or becomes hypertrophic. We must conclude that, in many cases, the mere abundance of nutritive matter in the blood is the cause of nutritive deposition; that is, of a kind of nutritive irritation.

As we know that, in the absence of sufficient nutrition, local irritation cannot cause hypertrophy, so we may understand how, nutrition abounding, secernent irritation may be attended with even great glandular hypertrophy of one kind or another.

The combination of local irritation and atrophy takes its explanation from or after these cases.

Irritation inducing absorption.—While a certain degree of local pressure or friction leads to increased nutrition, a greater amount of pressure causes absorption, as if by compressing the capillaries and arresting nutrition. And this process, whatever its nature may be, and whatever name we give it, will often be mixed up with, though

distinct from, nutritive irritation. A tumor may cause absorption on a spot of bone, and ossification around it.

The relation between absorption from capillary compression and that from general depletion does not seem to be very uncertain.

In what has been advanced, we may see ample grounds to distinguish between several modifications of one local irritation—as a puncture. First, that connected with simple, or excessive, or deficient reparation. Secondly, that which belongs to more morbid reparative acts, according as the body may have been previously, or may become subsequently deranged; and, thirdly, that which appertains specifically to the injury inflicted as in cases of great laceration or specific poisons.

The doctrines of *nervous irritations* hitherto have been rendered unnecessarily obscure, by mingling with them a variety of false or doubtful illustrations. The most common and positive case of nervous irritation is pain in, or referred directly to, a disordered part. And what are the effects of this on the constitution? How do ordinary measures of pain affect the healthy body? We had almost said not at all! But, on the other hand, a crushed finger to a feeble person in cold weather may be followed by severe rigor, fainting, and vomiting, and the injury to a limb, without loss of blood, may perhaps be followed by a fatal collapse. We are willing that such should stand recorded as one of nervous (sentient) irritation alone, but in every such case the strength of the body, the sudden effect on the respiration, heart, capillary, and muscular systems, must be traced out; and when, after the collapse, reaction comes to be studied, even the length of time that the patient has been exposed motionless to the cold, and every collateral circumstance, must be taken into the account. The effect of an extensive scald may be compared to the preceding case, and also that of the diffusion of fæces in the peritoneum. The last two cases we deem analogous to each other, except that in the first the chief morbid agent is soon removed, while in the latter it is more persistent. In both of these cases, however, it is essential to distinguish between the local capillary irritation tending to repair, and the nervous irritation which is, as it were, one step of another process, namely, that by which the body

generally may become affected. It is evident, also, that other influences tend to complicate the process. The exposure of the scalded surface, a process of depletion, and perhaps the absorption of prejudicial matters, require to be carefully appreciated.

Pain is said to be sympathetic, when, instead of being referred to the diseased organ, it seems to be seated elsewhere. Disease in the course of a sentient nerve seems to give pain where the radicles of the nerve are spread out; and this may be the explanation of many of the examples of sympathy, which are much more talked of than understood. Pain in the knee, from disease about the hip; the glans penis, from bladder disease; the inside of the thigh, from prostatic inflammation; and others may come to be thus accounted for. We have just dissected an example of sciatica dependent on medullary tumors along the right side of the loins and sacrum. We have known pains in the arm from phthisical abscess in the apex of the pleura. (See some account of pains in anginal attacks, &c. in papers on angina pectoris, by T. Wilkinson King, *MED. GAZ.* 1841, and of those of toothache, in the same journal, January 1842.)

Pains down the back of the leg, with disorders of the rectum, and along the inner part of the thigh with uterine diseases, seem to depend on local affections of the trunks of nerves; cramp also. There is evident reason to distinguish the various forms of pain in the head, side, back, stomach, and belly, but it is not easy to do so satisfactorily. We know almost nothing of sensibility within the pleura costalis, or in the substance of the brain, liver, spleen, and kidney. There appears to be something of definite distension in the side pains when we run after eating, and perhaps in the pains of stitch, cramp, and colic. On the whole, however, the more we know of pains, the less we know of their dangerous sympathetic effects. Pain over the shoulder has not yet been shown to depend on the liver or the stomach. Such a case as bowel irritation tickling the nose has no foundation, but such as we shall presently explain. A partial sign, and a regular sympathy, are very different things. The constitutional irritation of worms in the bowels is at present mere hypothesis. The delicate frame

may be infected, but myriads of the robust of all classes throughout the world are not less so, and without any sympathetic disturbance. Among the children of Jamaica, vegetable food, large bellies, multitudes of worms, and good health, did not appear to us in the slightest degree incompatible; and the same seems to hold on the continent of Europe. Our friend, Dr. Arbuckle, a very competent observer, assures us that one or two hundred lumbrici, of there or four inches in length, are sometimes voided at once, in Maranham, South America. He found tonics benefit the health of those who were put under his care under such circumstances, but that worms were too universally present for him to attribute any material or specific mischief to them. He regarded their increase as a consequence of declining health and vigour. He knows of no pathognomonic signs of worms beside the actual observation of them. It happened, though very rarely, that they were evacuated by an abscess. The people were not well supplied. Rice, vegetables, and salt fish, or salt meat, are their usual food.

It ought, we think, to appear a very difficult question with certain pathologists and doctors, that the irritation of worms may do so much harm, and harm only; while that of medicine, which is so much more evident, should be productive of so much exclusive benefit.

The *recherche* of M. Louis on *Tenia* presents a very good account of the symptoms of declining health, which alone are the cause of bringing the worm patient to the physician. Beyond this, his cases, we suppose, only constitute one more instance of misapplied statistics—of unequal facts, with feeble and erroneous views.

States of the tongue.—We cannot but regard the theoretical deductions commonly made from the appearance of the tongue, with reference to the rest of the system, as particularly fallacious. A natural tongue, doubtless, indicates healthy secretion; a furred tongue simply indicates undue secretion, and may very naturally accompany the increasing nutrition of the whole body. If it belongs to any kind of irritation (besides excessive secretion), it is to that of local and general hyper-nutrition. The clear and glazed tongue, said to be indicative of bowel irritation, although often

no disturbance of the bowels exist, indicates only disturbed and declining secretion, with failing nutrition. The whole mouth shares the like alteration; tenderness and ulceration follow. Perhaps the larynx is similarly affected, and of course its sensitiveness betrays a different kind of irritability. Variable catarrh may be superadded. The bowels may be affected together with, or instead of, the air tube: but the glazed tongue may be attended with seemingly good digestion, as in a case of psoas abscess, or open (compound) fracture.

These remarks may tend to show that, while general deductions may be admissible with care, the true meaning of the states of the tongue is limited, and that they have no specific sympathetic connexion with those of the stomach or intestines, and their only just import (in reasoning), depends on a precise local estimation which subsequently assists to explain the general state of the body. A dry tongue almost explains itself. A simply furred tongue, then, implies a degree of secernent irritation, just as the increasing plumpness of the individual signifies a nutritive irritation. It is the decline of the secretory and nutritive actions that belongs to a red polished tongue, and if there be any peculiar irritation in the case locally, it is one of sense—imperfect nutrition and tenderness, approaching to ulceration. We shall hereafter see that the general or constitutional indications correspond to that which we deduce locally.

Itching of the nares belongs to a similar state of body to that which the morbidly clean tongue evinces; that is, a condition of deficient nutrition and secretion, with augmented or disturbed sensibility. Here varying dryness, and irritability through a sensitive nerve are mere local effects which indicate the diathesis; and just so far only as they partake of the circumstances of the entire body, they present an example of sympathy; just as the banks of a river dry and crack when its source-fountains are low: the mud sympathises with the want of clouds and rain.

The same kind of explanation seems a sufficient account of certain affections of the skin, anus, &c. The local irritation of anal worms is regulated in

part by the vigour of the individual. A catarrh of the outlet, to which the feeble are liable, enables the creatures to be much more troublesome. A wasting and sensitive body is so much the more disturbed by them. Such a case of nervous irritation does, I believe, cause grinding of the teeth, by a reflex function, just as it may produce restlessness, starting, or a cry in sleep. Simple cutaneous irritation belongs to increased sensibility, to wasting, to the habit of scratching, and to the want of sound rest and full occupation.

More complicated forms of irritation of the skin may, at least in part, admit of explanation, by reference to humoral changes in the blood, as those of the spring of the year, or occurring at certain periods after exposure.

The irritation of teething must be investigated in the same cautious manner we have prescribed for other cases. Toothache is not generally supposed to excite any sympathies. Disorder of the dens sapientiæ often seems to induce a kind of earache. Active inflammation, from a cold, affecting the root of a tooth, subsides or gives rise to abscess, which will increase till its contents escape, and then it subsides. This may recur repeatedly; or a sequestrum and cloaca form, with a mass of exuberant granulation at the external opening, which mass, like that at the orifice of any granulating sinus, varies with the states of the body. With moisture and attrition the tumor may attain a larger size in the mouth than elsewhere, though never much larger than a marble. A similar tumor forms externally, in connection with salivary fistula; and, of course, with necrosis of the jaw, a fistula in the cheek with such a fungus would most probably be cured by extracting a tooth, so as to form a free opening for matter internally.

It is said that a superficial ulcer of the lip or face may be kept up by a diseased tooth irritating a nerve; and herpes of the face by teething. This requires very strong proof. The tooth may be removed, and the ulcer heal; but the one is not yet proved to be the cause of the other. Solitary and rare facts do well enough to support an imagination, but realities ought to have some more ostensible corroboration.

A state of the teeth, or rather of their connections, usually called irritable, that is, morbidly sensitive, and ready

to inflame and ache, is indicative of failing nutrition, and that is premonitory of toothache, as of various general disorders which taking cold may quickly induce. The inflammation will require its specific treatment; but the cure depends on augmenting the free nutrition, and obviating the causes of inflammation both locally and generally.

Cough depends on laryngeal sensitiveness, and it may be caused by excessive secretion, with or without declining nutrition of the mucous surface, or increasing sensibility of the part. Cough from sympathy with the lungs or stomach must remain to be first proved to exist, and then we may endeavour to explain it. "Stomach-cough" implies, as we suppose, a fair digestion temporarily aggravating a bronchial catarrh. When the body begins to waste, where should we so soon look for hæmorrhage (after the gums) as to the larynx, which is so delicate and vascular, devoid of cuticle, and incessantly exposed and in motion?

The most distinct examples of reflex function (excito-motory or other) constitute an established class of nervous irritations. It is necessary, however, to remember, that some supposed instances may be altogether erroneous assumptions on the part of those who are too exclusively wedded to a single principle.

A blow on the epigaster, causing collapse or death, is a much-vaunted instance of nervous irritation, but whether justly or not we cannot decide. We have elsewhere* suggested a different explanation. We are not sure, however, that the case is so well established as to deserve even a place among unexplained and rare phenomena. It is much more certain that men fall dead without any blow; as in cases where the openings of the coronary arteries become contracted after inflammation. Our friend, Dr. Joseph Ridge, possesses some histories of this kind, with one related by us. Those violent shocks which involve the cerebral, respiratory, and circulatory functions indiscriminately and almost universally, are not, we think, to be explained by a single word, unless by such a general term as disorganization.

Cerebral irritations, if attentively considered, seem still to require a good

deal of analysis. Perhaps, in strictness, we ought to consider separately all excito-motory phenomena, whether of health or disease; but these and such cases as the *indirect* dependence of the heart upon the brain, cannot yet be easily isolated in the study of medicine. Fear paralyses the voluntary muscles, and the blood sinks in all the veins, and fails in the cheek and head. A returning and increased current in the heart flushes the face, and even induces palpitation. These are complicated results of cerebral disturbance or irritation, but they admit of explanation in different degrees without much difficulty, and with great advantage.

Vomiting from injury of the head, or from obtuse pain or fainting, is an instance of irritation which may be called cerebral. The motions of swinging in the air, rotating the body quickly, or rocking at sea, seem analogous instances. Fear, collapse, disgust, and poisons, as antimony, whether put into the stomach or into the veins, all seem to act in a manner through the brain, in addition to excito-motor agency. Females seem more subject to sea-sickness than males, the young and aged more than the middle-aged, and invalids more than the robust. Cats, dogs, fowls, pigs, horses, and cattle, suffer, the young more than the old. We deem the affection to consist in a primary affection of the brain. Giddiness is often experienced early. Of course the only remedy for the disorder must be either to remove the cause or inure the sufferer to its effects. Perfect rest, reclining, with the head on its side, or the face upwards, decidedly assists to prevent the distress, and even to remove the feeling when it has commenced. A certain degree of repletion, and even a stimulating diet, help to maintain the powers of resistance, and obviate the tendency to debility which militates against recovery. The last attacks on a voyage may be expected before breakfast, and if the sufferer have to wait unusually for his dinner, he may find by experience, as we have done, that it may be difficult to hurry from the table to his bed in order to keep down the much-required meal; yet after an hour or two, with advancing digestion and vascular repletion, he may walk about with im-

* In the article on Angina, already cited.

punity. The wine-drinker has not to wait so long for the assimilation of his less enduring support.

We venture to class all pains under the term cerebral irritation, and also all excessive sensual and mental impressions.

The known excito-motory acts of the body may not on any account be employed to elucidate pain, or any disturbance which is not muscular, or dependent on muscle. They have nothing to do with mere sensation, and we ought to consider the philosophy which ascribes general convulsions to dental or intestinal irritation as at least very unsatisfactory — vague and indiscriminating, if not totally erroneous, since the only known cause of general convulsions is determinately in the nervous substance.

Spinal irritations may be well deserving of investigation; but we should blush to rank ourselves with some writers on this hypothetical ground. With organic lesions of the medulla and its sheaths we find here uniform signs, and there none, and so occasionally of the brain, but how different are the imaginary effects of what some call spinal irritation!

Hysteric irritation, and corresponding states in the other sex, are not simply nervous derangements; nutrient waste, and humoral deterioration and various visceral disturbances, are prominent features of the case, when the investigator is not engaged by prejudice.

Dr. Bright, in the 22d volume of the *Medico-Chirurgical Transactions*, has described some fatal cases of spasmodic disorder connected with pericarditis, and seems to think, with just caution however, that inflammatory or irritative action involving the phrenic nerve may have been the cause of the spasm. We have noticed such a case, in point of fact, but are far from admitting the explanation.

One prone to pericarditis is liable, though not equally it may be, to inflammation (in the same form) of any serous membrane, and when we find a more compound nerve, as the par vagum, divided by the pressure of an aneurism (as every now and then happens) without any spasm, we may not conclude, without good grounds, that slighter or even uncertain affections of a motor nerve can give rise to fatal *chorea* or *cataplexy*.

Much has been written concerning

various indefinite sympathies between the kidneys and brain or spinal marrow, but we should first seek for a full explanation of all inflammations dependent on diseased kidneys; 2dly, for an account of the effects of nervous paralysis on all secretions; and, finally, the residual facts may perhaps be set down to the credit of the doctrine of nervous sympathies.

The occult part of pathology, like astrology of old, has had too great attractions for some, while simple facts and inductions require more patience than it is often agreeable to bestow on them. Paralysis of the abdominal muscles may surely have some influence on the secretory viscera; and defective digestion, secretion, and sanguineous depuration, are but a part of the intricate problem in such a case.

Constitutional irritation or general disturbance, in connexion with local or specific injury, although an extremely difficult subject, may yet admit of some analysis and elucidation upon the foregoing principles.

EMPHYSEMA OF THE INTERNAL ORGANS,

FOUND IN A CHILD AFTER HAVING LIVED
TEN YEARS WITH GENERAL
EMPHYSEMA.

BY DUNCAN R. M'NAB, Esq.
Epping.

(For the *London Medical Gazette*.)

A BOY, æt. 10 years, labourer's child. His mother states that, at the age of four or five months, he had a severe illness, with great difficulty of breathing; that a blister was then applied to the chest; that from that time he has always been in a weak state of health, and his breathing short; that he became very puffy or full, so that, when she pressed her finger on his face, a pit would remain about two minutes; that at the age of 7 years he was brought home from school in a fainting fit, which lasted about five minutes; that from that time he used at intervals, first of four or five, latterly of one or two, months to have fainting fits, about ten in the course of two days; that after the fits he used to lose the puffiness (which she took to be fat, but which a neighbour told her was wind-dropsy),

and to become quite thin, but the fullness used gradually to come on again.

Feb. 23.—On account of the increasing frequency of the fits she brought him to me, just after the fits had left him. I did not then learn the above particulars. He took Hyd. c. Cr. gr. ij. ter die, about a fortnight, during which time he did not, as usual, become puffy, but rather thinner; the mother thought him better, and did not bring him any longer. She states that after the treatment was discontinued he gradually became again very full, till he was seized with the illness with which he died.

Nausea, pain in the head, pain in the bowels, and constipation, were at first the chief symptoms. He died in about ten days in a typhoid state, with delirium, coma, and bloody evacuations.

Post-mortem examination, 30 hours after death.

April 22.—Spleen dark coloured, large, crackling under pressure, and, on being cut into, giving out air-bubbles.

Stomach.—At the fundus two patches of air-bubbles, of the size of common shot, apparently between the mucous and serous coats: the muscles at the fundus red, and very distinct.

Gall-bladder.—Its coats very emphysematous; the contained bile very dark coloured.

Liver.—Pale; extending below the ribs and over into the left hypochondrium; on the right lobe were seen patches of minute air-bubbles, at first looked upon as a solid deposit; and on cutting into the substance of the right lobe the same were seen throughout; by pressure they might be squeezed out, and thus quite removed, or different patches might be united.

Kidneys.—The same may be said of the cortical substance as of the right lobe of the liver; there were also larger air-bubbles on the surface.

Pericardium.—A few large air-bubbles upon its outer surface.

Lungs.—Both pale and emphysematous throughout; the left with interlobular emphysema, and on its posterior surface extensive adhesions to the walls of the chest.

The mesenteric glands generally were much enlarged; suppuration had taken place around two of them, near the

ilio-cæcal valve; two inches below which, and about twelve inches above, the mucous membrane was of a dark red colour, with numerous white papillary eminences, and deep ulcerations around the larger glands. A lumbricus teres lay above the valves.

Epping, May 10, 1843.

OBSERVATIONS ON SEMINAL AND OTHER DISCHARGES FROM THE URETHRA.

BY BENJAMIN PHILLIPS, F.R.S.

Surgeon to St. Marylebone Infirmary, and Lecturer
on Surgery at the Westminster Hospital
School of Medicine.

(For the Medical Gazette.)

It is now many weeks since I forwarded to you two communications having reference to the subject of involuntary discharges of spermatic fluid. And as those communications have considerably enlarged my experience, and that in comparatively a very short time, so as to enable me to bring the cases more vividly to my mind than I could do on a former occasion, I have concluded that the results of my experience on the subject during the last three months might go far to shew the value of the remedy to which, on those occasions, I endeavoured to direct attention.

The number of cases which have come under my notice since that time amounts to 33; of these, 23 have been medical men—some in practice, others in *statu pupillaris*. In 24 instances it was admitted that masturbation had been practised; in some cases so frequently as twice or three times a day, but in all those cases it was stated that the habit had been abandoned. In two cases it was said that masturbation had never been practised: supposing that to be true, then the only way to account for the discharge was to assume that irritation was set up by a natural phymosis. We frequently see, even in young children, that when there is inability to uncover the glans, the secretion around the corona glandis does become acrid and troublesome. Whether in adults a similar irritation will of itself induce spermatic discharges, is to me very doubtful: I can readily understand that it may induce masturbation. In two cases the affec-

ion was said to be the result of sexual excesses. In two cases the only apparent cause was stricture. In one case the cause seemed to be a frequent indulgence in reading lascivious books. In one instance the genital excitement resulted from study, or from the perusal of works of imagination.

Such have been the probable causes of the complaint. Its urgency was very variable; in some cases the discharge did not happen more than once in a week or ten days; in others daily; in others twice or even three times a day. The effects on the constitution were not less variable. In one case, where the discharge happened commonly three times a day, and where it had continued more or less for twelve years, the patient being at present 24, the buoyancy of his frame was very little disturbed; he could walk eight or ten miles without fatigue; whilst in other cases, where it happened once or twice a week, the physical and moral impression has been most profound. Much of this, no doubt, results from the hold the complaint obtains upon the apprehension of the patient.

In two cases the complaint coexisted with epilepsy; what direct relation the diseases bore to each other was not very evident. In two cases there was very considerable digestive disturbance; flatulence and irregularity of the bowels were much complained of. In most of them there was constipation; and unless that was carefully attended to the genital distress was increased. In five cases palpitation of the heart was complained of; in four, "swimming" sensations in the head, failing memory, inability to apply to any thing. I cannot help thinking that, in some cases, the alleged failure of memory is owing to the intense pre-occupation of the mind with the complaint, and to the little impression which any other subject makes on it. Such have been the grand features in the cases to which I have referred.

With respect to treatment, the following are the results. Seven are at present under my care; five I think are doing well, two are not so satisfactory. Of the twenty-six cases which are off my hands, eighteen have been more or less completely relieved; in eight instances no sensible permanent *good was derived either from caustic or other remedies, though there was*

complete remission of the discharges for many days. In more than one of those cases I suspect the mischief has been kept up by some imprudent but concealed habit. In one case, I found the patient lay in bed till mid-day, or even later, and that the discharge generally came on once or twice between 9 and 12 o'clock. I have no doubt it was caused by conjuring up mischievous images. I requested him to get up at 9 o'clock, and the evil was, for the time, at once stayed.

With respect to the plan of treatment I employed, it depended on the circumstances of the case. In seven cases no acute pain was felt any where during the passage of the bougie; in one it occasioned a feeling as if a seminal emission was about to occur. In those seven cases I was content to try the effect of the bougie smeared with mercurial ointment, or merely oiled, and introduced twice a week; but although there was, in several cases, a considerable improvement, complete relief was obtained in only two instances. In nineteen instances I used the caustic. Of these cases ten were completely relieved by a single application; in three the amelioration was decided, though the complaint was not cured; in six there was no relief. In the nine cases in which the first application was insufficient, the remedy was again used—in three cases with complete success, in six without any evident amelioration; so that it succeeded in two-thirds of the cases in which it was applied, a result which, if confirmed by succeeding experience, would stamp it as a remedy of great value, though less certain than my previous impressions had led me to think.

On no single occasion have I known a patient to complain of the pain attendant upon the application of the caustic being severe; in many instances it did not seem to be greater than that of the inconvenience of introducing a bougie. In one single instance only did I experience any after trouble. A patient had caustic applied, without complaining of suffering; in four days afterwards he came to me with retention of urine. On the previous day he had walked far, and ate a good dinner, and it was after that he found a difficulty in passing urine. In many cases a little blood, usually a drop or two, has escaped on the next

occasion of making water after the application; but sometimes it has occurred two or three times. In no case have I known the discharge which should follow the use of the caustic extend beyond a week, and usually it is very trifling. I believe the remedy is much more effectual when it induces a pretty copious discharge.

My summary then is this: the caustic was applied in 19 cases: in 13 it succeeded, in 6 it failed; but in no case was there any aggravation of the symptoms; in no case was any complaint made of the amount of pain attendant upon the application; in only one case was any after inconvenience complained of. In several cases some drops of blood escaped with the urine; in some cases there was scarcely any appearance of discharge after it; in no case did the discharge extend beyond the seventh day.

It will be observed, then, that though the amount of good derived from the use of caustic is considerable, it is by no means a specific; but there is one class of cases in which the effect is remarkable; those in which very excited sensibility exists beyond the curvature, the disease seeming to depend upon the irritability seated in the vicinity of the opening of the ejaculatory ducts. In some cases this is so remarkable that the passage of a bougie over the part may actually induce emission. There are, however, many cases in which no such pain is discoverable, and in those cases I have not so much confidence in the efficacy of the caustic. In those cases the exciting cause of the emission is often habit. Masturbation or excesses having been long continued, the secretory action of the testicle is increased in proportion to the frequency of the calls made upon it; the vesicles are always full, the ducts are lax, and the fluid easily pressed forward. These cases improve under constant changing, occupation for the mind, and general tonic treatment. In one instance I have observed great good to result from the use of the tincture of cantharides carried to the extent of determining heat at the neck of the bladder, but in other cases I have known it fail.

I might allude to other plans of treatment, but as the present paper is merely a complement to the other, it might seem out of place.

CLOSURE OF THE VAGINA.

To the Editor of the Medical Gazette.

SIR,

ALTHOUGH I do not always approve of hasty comments on cases reported in our journals, I have been prompted to offer a few brief sentences on the cases of "Closure of the Vagina" quoted from an American journal in your number for the 12th inst.

Congenital adhesion of the labia in infants is not unfrequent: at the Royal Infirmary for Children I have had, occasionally, more than one case presented to me on the same morning, which I have not hesitated instantly to relieve.

Congenital adhesion is merely by a thin *film*, the division of which requires no *cutting*. A common probe pressed on the fissure from behind instantly relieves the labia, without any expression of pain by the child.

The epithelium is somewhat thinner in the line of the adhesion, as it usually is, indeed, when not exposed to the atmosphere. Spermaceti ointment on lint removes all irritation, if there be any, in two days.

The cases of Dr. Nott, it is stated, were adhesive *subsequent* to birth. This is, I believe, always as easily relieved without cutting, the adhesion not being the effect of plastic lymph, but a glutinous oozing probably from the follicles at the edge of the labia.

I should not have troubled you with these remarks were it not for the irritating effect often resulting from the retention of a few drops of urine, or of mucus, behind the adhesion, and the perfect simplicity and painlessness of what can scarcely be termed an operation.—I am, sir,

Your obedient servant,
WALTER C. DENDY.

May 19, 1843.

REDUCTION OF HERNIA.

To the Editor of the Medical Gazette.

SIR,

I SEND you the following case for insertion in your journal. The patient

was a most unfavourable subject for an operation, and was relieved by a plan of treatment which, I understand, has been very successfully adopted in Ireland, and which, I hope, in many cases may prevent the necessity of having recourse to a painful and dangerous operation.—I remain, sir,

Your obedient servant,

CHARLES COLLAMBELL.

Canterbury Place, Lambeth,
April 19, 1843.

Mrs. Russell, æt. 51, very corpulent, ruptured herself on the right side twenty-four years since, in lifting a heavy weight, and (until within a fortnight) has not worn a truss for the last seven years, but, in consequence of its being improperly applied, has constantly had it on with the rupture down; she has not experienced much inconvenience, and has always been able to reduce it in the recumbent posture until this afternoon at three o'clock. I was requested to see her at half-past eleven P.M., April 12, and found her extremely exhausted; countenance very anxious and shrunk; constant vomiting; pulse small and thready; hands and feet cold; breathing hurried; abdomen very tender, but not tympanitic. On examination I found a protrusion of intestine through the femoral ring, larger than I could cover with my two hands, very tender, and excessively tympanitic (giving the sensation of a bladder distended with air), and no impulse on coughing. I endeavoured by very gentle manipulation, for nearly half an hour, to reduce it, without success; and as she was in a very small room, and without the possibility of having a warm-bath, I advised her removal to the hospital. This she positively refused, as she was resolved not to submit to an operation. Under these circumstances I determined to adopt the plan of treatment recommended and successfully practised by Dr. O'Beirne. I introduced the elastic tube of the stomach-pump into the rectum, and passed it on to the distance of twelve inches. I then attached the syringe, and slowly injected two quarts of warm water. When half this quantity had been thrown up a gurgling was distinctly heard in the tumor, and it gradually became less tense. Having injected all the water, I removed the syringe, and allowed the

water to run off by the tube. I then reapplied the syringe, and continued exhausting the air, when, after a few minutes, I had the gratification to find the hernia gradually subsiding; and by keeping up gentle pressure the contents were returned into the abdomen. My patient immediately pronounced herself relieved; her countenance became cheerful, and the sickness abated. She was ordered a brisk aperient of sulphate of magnesia and peppermint water, and a dose of calomel and opium. The bowels acted freely on the following morning, and she is now as well as usual.

ON THE MECHANISM OF ABSORPTION.

To the Editor of the Medical Gazette.

SIR,

I SHALL feel much obliged by your giving insertion to the accompanying communication in an early number of your journal.—I am, sir,

Your obedient servant,

GEORGE ROBINSON, M.R.C.S.

Fellow of the Royal Medical and Chirurgical Society.

35, Hunter Street, Brunswick Square.
May 17th, 1843.

In a memoir which was read before the Royal Medical and Chirurgical Society in February last, I attempted to prove by a series of experiments that a partial or complete obstruction to the passage of the blood through the smaller vessels of the body will cause the escape of its albuminous portion through their coats. In the present communication I wish to direct attention to the influence which the opposite condition of the circulation exercises in promoting the absorption of any fluids that may be placed in contact with the external surface of the vessels, or only separated from them by one or more membranes.

If we examine the facts brought forward to illustrate the process of absorption, we shall find that the following is perhaps the only general conclusion that can be safely drawn from them, viz. :—

That no substance can exert any influence on the whole system, unless the circulation of the blood through the

vessels of the part to which it may be applied is performed with a certain degree of activity.

That the circulation of the blood must precede and accompany the act of absorption, is, among many other instances, proved by the following experiments:—

1. Magendie divided all the parts of the thigh of an animal but the femoral vessels, and then inserted poison under the integuments of the limb. While the vein was compressed no symptoms appeared, but they were immediately produced when the return of the blood was unimpeded.

2. Emmert tied the abdominal aorta, and introduced poison into a wound in the foot, but at the end of seventy hours no effects had appeared. On liberating the vessel then, the poison, prussic acid, acted within half an hour. I have repeated this experiment with precisely similar results. The aorta being compressed, a few drops of a strong solution of hydrosulphate of ammonia were introduced beneath the integuments of the thigh. At the end of seven minutes no symptoms had appeared, but on then releasing the vessel from the compression, the operation of the poison was immediately evinced, and the animal was dead in less than a minute.

A number of similar facts might be adduced in support of this assertion, but it will be sufficient to refer to those contained in all modern works on physiology: as Muller's, p. 254, &c.

This principle being established we may in the next place proceed to inquire how the action of the circulation in favouring or rather producing absorption is to be explained.

According to the laws regulating the transmission of stagnant fluids through the membranes, exosmosis and endosmosis should be continually occurring through the coats of the vessels of the lining body; and there undoubtedly analogous processes do take place. But it appears to me highly important that we should ascertain how far these laws are modified when one or both fluids are in a state of motion.

However, Magendie, and all succeeding physiologists who adopt his opinion, suppose, that the external fluid, permeating the membrane, makes its way to the internal surface of the blood-vessel, and is then swept on by the current of the blood.

According to this hypothesis the chief part of the process of absorption is made to reside in some peculiar power possessed by the membranous walls of the vessels; the circulating fluid itself being quite a secondary agent, though, as above mentioned, its motion is necessary for the action of any poison on the system at large.

To prove the truth of his opinion, Magendie performed an experiment. He passed a stream of water through a portion of carotid artery and jugular vein, having previously applied strychnine to the exterior of the vessels. In a few minutes the water discharged had acquired the bitter taste of the poison.

Now this experiment, considered by itself, throws but little light on the mechanism of absorption; it merely proves that while a stream traverses a membranous tube, any soluble matters placed on the exterior of that tube will be absorbed. But as to the relative influence of the stream and the membrane in accomplishing that end, we are left wholly in the dark. He referred the whole of the transmitting power to the membrane; but the same experiment will, I think, prove just as much the influence of the stream in increasing that power.

It has long been known that a fluid while traversing any porous vessel will draw in a considerable quantity of air, which is liberated when the fluid is again at rest.

I now quote an experiment from Sir J. Leslie's *Elements of Natural Philosophy*, Vol. i. p. 364.

"If a cylinder 1 inch in diameter, and 3 inches long, be fitted into an orifice at the bottom of a cistern, and on its upper side, at the distance of half an inch from its origin, a narrow arched glass tube be inserted, having its long end carried down to a basin of water 3 feet below the insertion of the other end, when a stream traverses the cylinder with a velocity of nine feet per second it will raise the water up the glass tube to the height of two feet, and if the tube be shortened within that limit, the basin will, in a short time, be emptied of the stagnant fluid. I have now several times repeated this experiment, and, with a rapid stream, the results were always in accordance with the above statement. Having filled a wine-glass with coloured fluid, and having connected its contents (by means

of a bent tube twelve inches long) with the interior of a pipe half an inch in diameter, I found that the glass was drained of the stagnant fluid in less than two minutes after the stream was turned through the pipe. I may refer to the same page for a proof of the statement that this imbibing power of the stream is proportioned to its velocity. I will, however, mention one other proof. While a cistern is full, the rate of discharge and consequent velocity of the stream through the orifice at its bottom will of course be greatest. Now if the apparatus above described be fitted into a pipe connected with this orifice, it will be found that the stagnant fluid will rapidly rise to a certain height in the glass tube; but as the depth of the column of water in the cistern diminishes, the fluid in the tube will oscillate, and fall till the stream becomes so tardy as not to exert any marked influence on the stagnant fluid. Having now proved the existence of this power, and also that it is proportioned to the velocity of the stream, the first step towards the application of the principle to the explanation of the process of absorption in the living body is to shew that the same force, whatever it may be, will act through one or more membranes.

Accordingly, the short end of the glass tube being covered with membrane, and its long end immersed in a coloured fluid, I found that within five minutes after the stream had commenced to flow, the whole of the air present in the tube (which was twelve inches long, and its bore $\frac{1}{4}$ th of an inch wide) had been absorbed, and its place supplied by the coloured fluid. A continued slow ascent of the latter was still proceeding when I was compelled to stop the experiment. I repeated it again, covering the short end of the tube with two membranes instead of one, but using a tube several inches shorter than in the last case, and found that there was a very slow but steady and constant flow of the fluid towards the stream; the fluid which thus traversed the tube being opposed in its flow by gravity, and being itself of greater specific gravity than that of the water constituting the stream. By these direct experiments, and from a careful consideration of the chain of indirect evidence furnished by a number of morbid and healthy actions that

are known to occur in the bodies of animals, I am, I think, justified, even in the present incipient stage of the inquiry, in making the following statement:—

That as it has been shown that the effusion of albuminous matters through the coats of the vessels of the living body is produced, and modified in its nature, by the degree of the compression of the blood contained within them—this action being independent of, and even in opposition to, the ordinary laws of exosmosis, deduced from experiments on *stagnant* fluids—so I believe the chief part of the process of absorption in animals to arise from, and depend on, a force existing within the blood-vessels; that force being generated by, and proportioned to the velocity of, the moving mass by which, in a healthy state, they are incessantly traversed.

That something like a suction power acts in promoting or causing absorption is undoubtedly a very old opinion, and the truth of this remark is evident in the literal signification of the word itself. But so far as my present knowledge extends, all previous writers have referred that power either to the enlargement of the chest in inspiration, or to the dilatation of the ventricles.

Now while readily admitting the influence of these actions in facilitating the return of venous blood, and thereby indirectly favouring absorption, I cannot think that they exercise any immediate effect in promoting the entrance of extraneous matters through the coats of the smaller vessels. But if, on the other hand, we suppose this suction power, whatever its precise nature may be, to be caused by and reside in the stream of blood, to be greatest wherever the current is most rapid, to be increased in its activity by whatever accelerates the velocity, and diminished by whatever induces a retardation of the circulation through any part, then we shall have a principle of action at once simple and efficacious, in perfect accordance with the established laws of hydraulics, and by the operation of which many morbid and healthy phenomena of the human body can be satisfactorily explained and readily understood.

In the present stage of the inquiry I shall not make many applications of this principle, but content myself with briefly alluding to some facts which

seem to corroborate the doctrine herein sought to be established.

Magendie proved that a state of plethora retarded, and one of depletion promoted, absorption. These two conditions of the system are evidently attended by two opposite degrees of activity of the circulation.

For when the mass of blood is much augmented, the obstacles which naturally oppose the free passage of the blood through its vessels are materially increased, at the same time that the action of the heart is slower and more laboured than usual: consequently the proportion then existing between the moving power and the mass to be moved is unfavourable to a rapid circulation: and we may thus explain the slower action of poisons after he had injected a quantity of water into the veins.

Whereas, after bleeding or any other large depletion, the whole of the arteries contract as the quantity of blood in the system diminishes, so as to form a series of narrower tubes; and the heart being relieved of a part of its load, after the first shock is over, increases the rapidity of its contractions so much, that a more rapid circulation must necessarily result.

There are two parts of the animal economy where the process of absorption is actively carried on, and where some beautiful modifications of this principle are exemplified. I have said that compression of the blood within its vessels favours effusion: it should follow, therefore, that the compression of an external fluid against their coats, while they are traversed by a rapid stream, should promote absorption; and such doubtless is the case.

The influence of pressure in causing the absorption of effused fluids is well known, and its application is seen in daily practice. In the intestines, through which the body obtains all its nourishment, some provision for increasing the absorbing power of the vessels was required, and, accordingly, is there found. Their peristaltic action keeps up a steady continued pressure of the chyme against the vessels, thereby regulating, to a certain extent, the quantity of fluid effused from the latter, at the same time that their calibre is diminished, and the velocity of the blood traversing them consequently increased.

It has been an interesting problem in
808.—XXXII.

physiology to explain how the fœtus is nourished by the maternal blood without any direct vascular communication existing. On examining the maternal vessels, it is evident from their increased diameter, great length, and tortuous arrangement, that the circulation through them must be much retarded; while, on the other hand, the shorter circuit of the fœtal blood, and the rapid contraction of the fœtal heart, render it highly probable, if they do not establish the certainty of the fact, that the velocity of the fœtal blood during its passage through the placental vessels is much greater than that of the maternal circulation.

Since, therefore, it has been shewn that the absorbing power of a stream is proportioned to its velocity, it should follow that, when two currents of blood, moving with different degrees of velocity, are in juxta-position with each other, being separated only by two thin membranes, the more rapid stream will not only draw in any fluid that the other may have already effused, but may even directly increase the quantity or rate of that effusion.

Wherever the course of the vessels is tortuous, or their coats relaxed, a retardation of, and consequent impediment to, the circulation of the blood results—effusion takes place, and absorption occurs very slowly, and *vice versâ*. We can thus understand why the surface of old ulcers should absorb more rapidly than that of more recent ones; why a ligature tied round the limb, or the application of a cupping glass, impedes the action of poisons introduced into wounds of the extremity.

In short, throughout the whole body, the two antagonistic processes of absorption and effusion are constantly in operation, the preponderance of the one or the other in any particular part being regulated by the facilities or impediments which the blood meets with in its passage through the *smaller* vessels of that part; and I believe that absorption takes place chiefly in that part of the circulating system, from the circumstance of the coats of the vessels being there thinnest, and the rapidity of the current greatest. As before stated, I consider these two processes to be, in their nature and causes, essentially different from those usually understood by the terms endosmosis and exosmosis, and to be, in a great mea-

sure, independent of the laws regulating the transmission of *stagnant* and *uncompressed* fluids through membranes.

Note.—Of course these remarks are only intended to apply to the general processes; for there is undoubtedly something more than a mere physical law in operation in all those parts where *secretion* is going on; and a certain selective influence is probably also exercised in regulating the admission of external matters within the circulation.

CASE OF
FATAL WOUND OF THE CHEST,
ACCOMPANIED WITH
DIARRHŒA AND DISTRESSING VOMITING.

To the Editor of the Medical Gazette.

SIR,

If you think the following worthy a place in the *MEDICAL GAZETTE*, you will much oblige the writer by its insertion.

D. M'PHERSON,
Surgeon.

John Maitland, æt. 32, of robust constitution and temperate habits, had been standing with a pitchfork in his hand, on the top of a cart laden to the height of sixteen feet with bundles of straw. The horse in yoke, being of a restless nature, took fright at some object, and making a sudden spring forwards threw the man and the fork precipitately over the hinder end of the cart. The pitchfork had fallen first to the ground, and, while resting on its harmless end, received the man from a height of three feet upon its prongs, one of which entered the left breast about two and a half inches below the mamma, and inflicted a severe punctured wound. An old woman had administered to him a glass of gin immediately after the accident, and he was carried to bed without having sustained any considerable loss of blood. On seeing the patient three hours after, an oval wound of the size of a shilling, and resembling very much the consequence of a pistol-shot, was discovered in the situation just described; but no symptoms were then elicited which could lead to the apprehension of the chest being entered. Pulse full and

excited; face flushed; skin hot, and bedewed with a copious perspiration; tongue covered at the root and centre with a layer of white pasty fur, and his wife says he has had diarrhœa for the last eight days; breathing hurried and anxious. A distressing sickness had continued since the time of the accident to occasion the vomiting of a tenacious frothy mucus tinged with blood; and his strength had been so much reduced in consequence, that he begged to be let alone, and lay in a state of apparent syncope during the intervals of the retchings. No spitting of blood, or escape of air or blood from the wound. Lies easiest on his back, and does not complain of any local pain.

On examining the pitchfork, which lay still on the spot where the accident occurred, a bloody mark, extending from the point up two and a half inches of one of its toes, was distinctly discovered, and the opinion of the chest being penetrated duly confirmed.

Mitt. Sanguis ad 3xviiij. To be followed up with the succeeding mixture:—

R. Tart. Antim. gr. ij. ; Tinct. Opil, 3ss. ; Aquæ font. 3viiij. M. fiat mist. cujus capiat. cochlear. mag. 3tiâ quâque horâ.

Wounds fomented with hot water, and dressed with adhesive plaster. On seeing patient on the afternoon of the following day, I found him almost *articulo mortis*, lying upon his back, and still making ineffectual efforts to vomit—a condition of things which, by the friends' account, had been unremitting since the period of my former visit. Respiration sonorous and abdominal; countenance collapsed and mortally pale; coldness of the extremities and great prostration of strength; sensibility to stimuli perceptibly impaired.

Ordered warm applications to the feet and chest, and administered at frequent intervals a little brandy diluted with water.

Went to visit another patient, and on returning a couple of hours afterwards found him still sinking. The eyes looked glassy; black sordes had encrusted his mouth and lips; and in half an hour afterwards, while in the act of changing his position in bed, he expired.

Autopsy.—The end of a gum elastic catheter passed readily down the course

of the wound to a depth corresponding with the bloody encrustation upon the pitchfork. On opening the chest, I found the instrument had entered between the sixth and seventh ribs, and, running an oblique course, had severely lacerated the lung, together with the inflicting a gentle puncture upon the floor of the diaphragm. A considerable quantity (5 oz.) of effused air and blood existed in the pleuritic cavity. A high degree of inflammation surrounded the wounds in the pleura and lungs, but no morbid appearances followed upon the rasure of the diaphragm.

REMARKS.—The absence of certain pathognomonic symptoms, and the unobtrusive appearance of the external wound, would have led strongly to the conclusion that the pleura had not been injured; but the single evidence derived from an examination of the instrument by which the wound was inflicted proved the contrary of this, and set the question satisfactorily at rest. This would seem a case in point to add to the list of injuries to the chest, the nature and extent of which are not to be determined by the information derived from the nature of existing symptoms. The presence, to be sure, of certain pathognomonic symptoms affords decisive evidence of internal mischief being done; but their absence do not by any means assert the harmlessness of the injury. Here was a case in which there was no expectoration of frothy blood, no escape of air during expectoration, no emphysema, &c., and yet both the pleura, the diaphragm, and the lungs, were extensively and fatally wounded. The point most worthy of attention in this case was the incessant vomiting. Upon what connection between the digestive organs and the parts wounded, should the stomach be excited to such violent action as to continue its throes for a period of 24 hours in spite of medicine; to form the most aggravated symptom of the malady, and thereby lead to the fatal consequences which ensued?

Harrogate, May 17, 1842.

MR. BRUNEL'S CASE.

To the Editor of the Medical Gazette.

SIR,

THE public sympathy and curiosity respecting Mr. Brunel were but very imperfectly gratified by gleanings from the columns of newspapers. Medical men require information of a different kind; and now that that gentleman is happily released from his awkward predicament, they have a right to expect it from a better source. Inasmuch as their efforts to raise medicine from a conjectural art to the rank of an exact science have, in a great measure, been crowned with success, they may well be excused from reposing implicit confidence in the meagre, unsatisfactory, and unauthenticated letter upon the subject which appeared in the *Times* newspaper, and which may possibly have emanated from a non-professional person and incompetent narrator. Assuming, however, that the anonymous statement in the *Times* is substantially correct as far as it goes, it is quite clear that Mr. Brunel's case presented some features of very great interest; and it is highly desirable that they should be fully considered and reported upon by one of the eminent surgeons who assisted him. I shall refer to one of the symptoms only to illustrate my object in thus trespassing upon your columns.

We are told that after the operation of tracheotomy the forceps could not be employed from the extreme irritation of the trachea. This is, I believe, almost a singular instance of the kind. Magendie opened the trachea of a dog, and, upon passing whalebone up into the glottis, much coughing and irritation were produced; but, upon passing it downwards through the trachea, no inconvenience ensued. A woman had a triangular portion of a sheep's vertebra impacted in the right bronchus, below the clavicle. Mr. Liston opened the trachea, and with some difficulty extracted the bone by the forceps. Not being then aware of Magendie's experiment, I was particularly struck with the very slight inconvenience felt by this patient, and subsequently by others, on the insertion of the forceps.

At a meeting of the Medico-Chirurgical Society, held about three years

since, the subject of tracheotomy was introduced by Mr. Travers; and in the discussion which followed, the comparative non-susceptibility of the trachea was fully insisted upon by Sir B. Brodie, Dr. Marshall Hall, Mr. Liston, and others. An illustrative case given by Mr. Liston on that occasion is worth repeating. A man had some chronic disease about the larynx, which obstructed respiration. The trachea was opened, and the long tube, which he wore in the opening constantly, produced no uneasiness. This man habitually relieved himself from occasional attacks of dyspnoea, by passing a long feather from the tail of a turkey down into the depths of his chest, and bringing up from thence long strings of tough mucus, which he did without causing the slightest irritation or cough.

Although phthisical symptoms generally supervene if a foreign substance be long retained in the trachea, the bronchi, or air-cells, there seems to be less danger from the irritation caused by its immediate presence there than from the obstruction caused thereby to the pulmonary circulation.

Whether the excessive irritability was merely a higher order of natural susceptibility, or was morbid sensibility, or was connected with inflammatory action, or with any other cause, is one of the points which remain to be cleared up in Mr. Brunel's case, upon which, I trust, we shall shortly be provided with an efficient memoir from the pen of one of his distinguished surgeons.—I am, sir,

Your obedient servant,

REGINALD BURRIDGE, M.D.

Physician to the Taunton and Somerset Hospital.

Taunton, May 20, 1843.

ON THE NATURE, DIAGNOSIS, AND TREAT- MENT OF INCIPIENT PHTHISIS.

BY CHRISTOPHER M. DURRANT, M.D.

Physician to the East Suffolk and
Ipswich Hospital.

(For the *London Medical Gazette*.)

SINCE the immortal discovery of auscultation by Laennec, perhaps no disease has more fully occupied the atten-

tion of pathologists than the one under consideration; and few indeed, it may be added, have advanced more progressively towards precision, or yielded more definite results.

The labourers in this extensive field have been by no means confined to a single country. England, France, Germany, America, and Italy, have alike honourably produced inquirers, who, by their zealous and successful investigations, have assuredly brought the diagnosis of phthisis, in its earlier stages, to a degree of certainty previously unknown.

The mortality caused by pulmonary consumption is estimated as producing at least one-fifth of the entire deaths in this country; which fact alone proves, with melancholy truth, the almost hopeless amount of benefit that we can expect to derive from medicine, save as a palliative in the *very advanced* stages of the malady.

That nature does occasionally, though rarely, bring the disease to a happy termination I am fully convinced; and as the views of M. Rokitansky, of Vienna, on this subject, are the most recent, I make no apology for introducing a somewhat lengthened quotation from the notice of his work on Morbid Anatomy, in the January number of the British and Foreign Medical Review for the present year.

This author has shewn that the phenomena of phthisis may proceed towards a curative termination by six different modes:—"1st. By a callous degeneration of the tissue around the cavity, or the formation of a membrane within it, like a serous or a mucous membrane; the former being usually found when the disease is tranquil; the latter when there is much irritation. 2dly. The cavity may completely cicatrize, its walls gradually falling in and uniting, with obliteration of the bronchi and sinking in of the surface of the lung, and perhaps of the wall of the chest also. 3dly. The cavity may, after partially shrinking, be filled by chalky matter, from the metamorphosis of some remaining tubercle. 4thly. In the place of the cavity there may be produced a large callous mass of tissue, like that of cicatrices. 5thly. The tubercle may not proceed to the formation of the cavity, but being arrested in its earlier progress, may diminish in size, and may be changed into a gray

or dirty white mass of chalky matter, and at last into a hard concretion. And lastly, at a still earlier stage, the tubercle being arrested in its progress, may retrograde and become *obsolete*, shrivelling into an opaque, blueish-gray, cartilaginous knot, which is indisposed to any further metamorphosis."

Such are the conclusions to which M. Rokitansky has arrived; to the correctness of some of which my own observations lead me to concur, more especially in reference to the occasional cicatrization of cavities, and the shrivelled condition of the tubercular deposit.

Nature of tubercle—This paper being professedly practical, my observations on the pathology of incipient consumption must necessarily be very brief. Without entering upon the multifarious theories that have been advanced, I may state that I believe phthisis to be caused by the deposition of an unorganizable matter from the blood, presenting the form of miliary granulations, yellow caseous opaque matter, or, thirdly, as tuberculous infiltration; which latter deposit, save in the cases of acute phthisis, less frequently obtains in the early stages of the disease. This secretion forming tubercle is closely connected with the strumous diathesis, either hereditary or acquired, and, according to M. Andral, appears especially influenced by irritation, inflammation, or congestion of the blood-vessels of the part in which it is earliest deposited.

The ordinary and primary seat of tubercle, as shewn by Dr. Carswell, is principally on the free surface of mucous membranes; and at the commencement of the disease the lesser bronchi, the air-cells, and the interstitial cellular tissue, appear peculiarly obnoxious to its presence. Of the origin of the miliary tubercle, or granulations of Bayle, many different opinions are entertained. That of Laennec, who viewed them as similar in nature to the yellow crude tubercle, but existing in an incipient or nascent state, may perhaps be considered on the whole as the most satisfactory. M. Rokitansky appears to maintain a somewhat similar opinion, and believes the peculiar form of deposit to depend upon the degree of the tuberculous diathesis which exists at the time. The tubercular gra-

nulations, whether deposited singly or in clusters, appear first, according to this pathologist, in the form of miliary grains, "or, in an intense degree of the tuberculous diathesis, it may be deposited at once as the yellow tubercle."

In tubercular infiltration, the deposit appears completely diffused throughout the cellular and interstitial portion of the lungs, presenting the appearance as if the matter had been poured into the lung in a liquid form, and had subsequently become solidified.

This tuberculous infiltration is considered by M. Rokitansky as "hepatization by a tuberculous product." He maintains that the ordinary deposit of a pneumonia, when occurring in a strumous habit, instead of being absorbed or becoming purulent, is gradually metamorphosed into the yellow tuberculous matter; and farther, that the change from the fibrinous to the tuberculous secretion can be distinctly demonstrated.

This tuberculous infiltration, in which are not unfrequently detected isolated portions of caseous matter, sometimes obtains in a more fluid form; this constitutes the *infiltration tuberculeuse gélatiniforme* of Laennec, and not a deposit *sui generis*, as has been supposed by some authors.

It is now, I believe, an undisputed fact, and one which we shall hereafter find to be of great practical importance in the diagnosis, that when tuberculous deposit in the lungs takes place gradually, in almost all cases, the superior lobes will be found first affected; and of these the upper and posterior parts are most prone. Upon what circumstance this increased liability to tuberculous deposit in the upper lobes depends, I confess that I cannot decide; neither has it, I believe, hitherto been satisfactorily explained. I do, however, conceive, that the rash exposure of the upper parts of the chest in both sexes, must, by exerting a local influence on the circulation in the corresponding part of the lungs, materially increase the power of the already existing cause, whatever that may be. Another curious and valuable fact, although of less practical importance than the preceding, is this, viz. that in the earliest period of tuberculous deposit the left lung is more obnoxious to the disease than the right. As the affection, however, increases, it will be

found to advance with nearly equal rapidity on both sides.

Diagnosis.—In investigating the earliest signs by which tuberculous phthisis may be detected, I may remark that it is my intention to limit my inquiry to the physical phenomena of the affection. The general symptoms are so ably and fully described by Sir James Clark, in his valuable treatise on Consumption, that to his work, especially his remarks on tuberculous cachexy, and to Dr. Todd's learned essay on strumous dyspepsia, in the Cyclopædia of Practical Medicine, I beg unhesitatingly to refer, as embracing all that can be said on the general symptoms of the disease. Notwithstanding the determined opposition and ridicule which the stethoscope long encountered in its earlier career, its value as a diagnostic agent is now, I believe, too fully admitted to require any comment.

I must, however, strenuously urge the necessity and incalculable importance of investigating the earliest and most incipient threatenings of the disease; for, as Sir James Clark graphically observes, "I do not hesitate to express my conviction, that by adopting a rigid examination on being first consulted, the greater number of cases of tuberculous phthisis would be discovered at a much earlier period of their course,—often, I am persuaded, many months, nay, occasionally years, before they now are, from the careless manner in which this class of patients is too commonly examined. In the present superficial mode of inquiry, it is too often far advanced, when the patient is said to be merely threatened with it, and tracheal or bronchial irritation are the terms employed to account for symptoms which a closer investigation would trace to a deeper source. We must not be satisfied with a few rough and slovenly thumps on the upper part of the chest, or even with the use of the ear or stethoscope for a few moments, applied as if we were afraid, rather than desirous of ascertaining the real condition of the lungs. Such superficial examination, if it deserves the name, is worse than useless: with the semblance of doing something, it really effects nothing, unless it be to deceive the patient and his friends, and bring this method of diagnosis into *unmerited disrepute.*"

Much of the apparent difficulty in

stethoscopic examination may be easily removed by adopting in our investigation a more regular and methodical method; and, with this view, I may preface my observations on physical diagnosis by a few remarks on the practical application of the instrument.

In performing auscultation several rules are to be attended to, affecting both the observer and the patient. In a first examination, especially in the female sex, a nervous alarm is very commonly excited, rendering the respiratory movements irregular, abrupt, and wholly inefficient for the purpose of a correct diagnosis. This state we must endeavour quietly to overcome; we must guide, but not alarm our patient, using as little parade as possible, "Avoid" says M. Fournet, "a stern air, an abrupt address, and solemnity; these throw the patient into a state of nervousness. There is a calm, simple, benevolent mode of accosting a patient, a certain gentleness and earnestness of manner, that at once wins his confidence, and renders him composed, so that he answers correctly, does what he is desired well; and then his features, influenced only by the morbid state, express accurately all he feels."

We must endeavour to give our entire attention to one sound at a time, avoiding with equal care any liability to distraction by surrounding noises. This faculty of concentration can, as I have personally proved, be greatly strengthened by habit, and then, like many other qualifications, it becomes more and more amenable to the will.

In examining the lungs in incipient phthisis the sitting posture is to be preferred; the chest should be moderately rounded, and if possible uncovered; this, in the infra-clavicular regions, can generally be effected without outraging the feelings of the most delicate. The arms should be allowed to hang unconstrainedly at the sides. After glancing at the general contour of the thorax, and ascertaining the facility with which the ribs rise and fall, we should direct the patient to breathe naturally, so as in the first place to become acquainted with the normal state of the respiration.

The examination should be always conducted slowly, not trusting too much to medical tact; at the same time it is incumbent on us to be extremely careful not to allow any preconceived

judgment which we may have formed to influence us in the investigation of the true state of the lung. The stethoscope should be applied firmly, but lightly, and in close proximity to the chest; all unnecessary rustling of the clothes must be sedulously avoided. The patient should then be directed slowly to take some deep inspirations, then a single cough, and repeated: this latter act will frequently enable us to discover the click of incipient phthisis, when other means have failed. Both sides of the chest must be examined in a precisely similar manner: this ought never to be omitted, however clearly and indisputably the disease may be indicated. In auscultating a chest where we have reason to fear deposit, the infra-clavicular, the acromial, the supra-scapular, and the axillary regions, will obtain our especial attention. Still, however, in a doubtful case, we must never rest satisfied until the condition of the entire chest has been patiently and carefully investigated. The physical examination of the earliest local signs of phthisis may be referred to three heads.—inspection, auscultation, and percussion. To each of these I shall briefly direct attention.

Inspection.—On baring the chest, and placing the patient in a direct light, at the same time taking care that he use no muscular exertion, we are not unfrequently enabled to detect a marked difference in the form and rotundity of the upper part of the chest. This in some cases is very slight, or even unobservable, while in others it amounts to indisputable softening or flattening of the infra-clavicular region. To this is sometimes added an insufficient elevation of the three or four superior ribs on one side of the chest. The difference, if not very appreciable, may occasionally be rendered more so by the application of the expanded hands simultaneously beneath both clavicles, when we often perceive, on directing a full inspiration, that the ribs on one side rise with elasticity, as in health, while on the opposite side they remain comparatively motionless.

These signs, of minor import when isolated, yet when combined with the evidences obtained by auscultation and percussion, tend to throw considerable light on a doubtful case, and as such should never be omitted in the exami-

nation. The causes on which the above phenomena depend, are, I imagine, to be attributed to whatever obstructs the admission of air into the minute bronchial tubes. This may arise from thickening of the tubes themselves; compression by tuberculous deposit; partial atrophy of the pulmonary tissue from inactivity, often increased by adhesions; to which should be added, wasting of the thoracic muscles.

With the above phenomena may be included the occasional occurrence of diminished vocal vibration, as perceived on applying the expanded hands, upon the upper parts of the chest. This becomes more apparent in those cases in which the tuberculous matter is deposited with the greatest rapidity, and confined *en masse* to the apex of the lung.

Auscultation.—I have selected the examination of the signs deducible from auscultation, prior to those from percussion, inasmuch as I feel persuaded, that, to a practised ear, the minute changes which take place in the respiratory murmur in the earliest stages of incipient phthisis are more appreciable, and more decisive of the disease, when investigated by the auscultatory phenomena, than when too implicit reliance is placed on the minute shades of dulness as elicited by the most careful percussion. For practical purposes the physical changes affecting the normal respiratory murmur, may be advantageously divided into those pertaining to the sounds of inspiration, and those proper to expiration.

I may in this place again repeat the importance of examining and concentrating the attention on each sound separately; at the same time carefully comparing the results with the phenomena observable on the corresponding side, and in other parts of the chest.

The murmur audible during the act of inspiration may be simply decreased in duration and intensity; for instance, if fixed at 10, the nominal healthy standard of M. Fournet, it may fall to 4, or even to 2; and in cases of rapid deposit may become inaudible. The same murmur frequently undergoes great alteration in character, conveying to the ear the impression of hoarseness, roughness, or dryness; the “rude inspiration,” of some authors. This depends principally upon compression of the

minute bronchial tubes by tuberculous deposit, thereby causing an undue vibration in the passage of the air to the terminal cells; it arises partly, also, from a thickened state of the tubes themselves.

The occasional abrupt or jerking rhythm of the respiratory murmurs depends in part upon the same cause, and partly, also, according to Barth and Roger, upon the impediment to the free expansion of the lung, in consequence of inter-current pleuritic adhesions. This want of continuity in the act of respiration I have hitherto only met with below the clavicles. Dr. Walshe, in his valuable little work on Physical Diagnosis, just published, states that he has detected this phenomenon, at the lower parts of lungs, whose summits and upper parts presented the signs of cavities. Jerking respiration is commonly confined to the murmur of inspiration; I have, however, in a few instances, found it of a double and treble character, accompanying the expiratory sound; the inspiratory murmur, with the exception of being harsh and dry, remaining unaffected. Abrupt respiration, especially when accompanied by dulness on percussion, and flattening or insufficient expansion of the infra-clavicular region, becomes a valuable sign of incipient tubercle.

The murmur of expiration is liable to marked alteration in the earlier stages of phthisis pulmonalis, and when present is likewise a valuable indicative sign of the existence of the disease. This murmur, which, in the healthy lung, is nearly audible, (although not completely so, as stated by some), is now greatly increased both in duration and intensity. Placing with M. Fournet the ideal standard of natural respiration at 2, it may become prolonged to 20, which this author fixes as the maximum; at the same time, it passes through the different gradations of quality and intensity, to the extent in some instances of entirely masking the preceding murmur of inspiration.

Independently of the changes to which the natural respiratory sounds are liable, auscultation frequently reveals other phenomena, which, especially when coexisting with those above detailed, prove of invaluable import in *the early diagnosis of this insidious disease.*

Under this head are included the various rhonchi audible in the different stages of the malady: for our present purpose it will suffice to notice those only which obtain at the very commencement of the affection.

These sounds may be divided into the dry and moist: the former being almost exclusively confined to the incipient stage alone of pulmonary phthisis.

Of the dry sounds are the sensations of crackling, crumpling, &c. communicated to the ear during inspiration; these, when very marked, not unfrequently appear to blend the sounds of inspiration and those of expiration in one continuous soft rustle. I have succeeded in very closely imitating this sound by loosely enclosing a small piece of tissue paper in a large silk pocket-handkerchief; this, when gently grasped and held near the ear, at the same time using alternate compression and relaxation, yields an indistinct crumpling sound, very similar to the one in question. The mechanism of the production of this sound is somewhat obscure; as, however, it has been heard only in the first stage of tubercles, its import as a diagnostic auxiliary is very valuable. M. Fournet states that he was enabled to detect the dry crumpling sound in the wards of La Charité, in the proportion of about one case to eight of incipient phthisis. My own experience hitherto is in favour of a smaller ratio than the above.

Another sound, which I have heard more frequently, and which appears to be a mere modification of the crumpling, is an occasional plaintive whining note, audible during inspiration only, and principally at the termination of that act. This latter sound occurs only at intervals, and in general requires a forced inspiration for its development.

The only other abnormal phenomenon whose pathological signification, when confined to the apices of the lungs is strongly indicative of commencing phthisis, is the pulmonary crackling, or moist sounds above alluded to. This consists of a succession of minute cracklings, audible only during inspiration. In its commencement, it possesses the character of dryness, differing but little from the crumpling sound already described; as the disease advances, the dry crackling gradually becomes moist, and is then indicative

of tuberculous softening. M. Fournet, who considers the dry crackling as distinct from the sound of crumpling, states that he recognised it in eight out of ten cases of incipient tubercular affection.

Such are the various rhonchi occasionally audible during the early stage of pulmonary consumption; and great as unquestionably is their diagnostic import, when present, still we must carefully avoid inferring from their absence (other indications obtaining) the non-existence of the disease. The only remaining physical signs revealed by auscultation are an increased resonance of the voice and cough, amounting even to modified bronchophony; together with an unusual distinctness of the sounds of the heart, below the clavicle; that viscus and the great vessels being at the same time in a healthy condition. These phenomena depend upon a condensation of the upper part of the lung, either by clusters of tubercles, by tubercular infiltration, by hepatisation, or by the three states combined, the two last being hardly distinguishable.

Percussion.—As already stated, the results afforded by this mode of investigation are not so early applicable to the diagnosis of the signs of incipient phthisis as the alterations in the character of the respiratory murmur; these latter frequently presenting, in conjunction with general symptoms, prior to the existence of any marked difference in the comparative resonance of the chest. When percussion, however, yields a dull sound, it may then, perhaps, *ceteris paribus*, be esteemed a more valuable indication of the disease than any of the foregoing signs, demonstrating as it does the positive deposition of tuberculous matter.

The amount of dullness, as elicited by careful percussion, varies greatly; in some cases a merely increased resistance to the finger is alone appreciable, while, in others, the sound resembles that obtained on percussing the thigh.

In conducting the examination, a few general rules may be advantageously borne in mind.

The position of the patient, as during auscultation, must be unconstrained, the arms being placed exactly in the same position; as the bulging out of the chest, or irregular contraction of the pectoral muscle might materially modify the

sound, and thereby lead to error;—the chest, if possible, should be uncovered, or, if covered, the same thickness of linen should be maintained, carefully avoiding folds. Mediate percussion is preferable to immediate; while a light smart tap, frequently repeated, yields a much more delicate and accurate result than a heavy stroke. I have invariably found the index finger of the left hand the best pleximeter, and a clearer sound obtained by striking its palmar than its dorsal aspect;—the depression immediately below the clavicles yields a more accurate result than by tapping the bone itself;—in doubtful cases all the regions of the chest should undergo a careful examination, as well by percussion as by auscultation; the great practical rule, however, to be followed, is to *immediately* compare the resulting sound with that elicited from a *precisely* corresponding situation on the opposite side, striking, with the same firmness, and *perpendicularly* upon the finger.

The minute shades of difference in sound may sometimes be rendered more apparent by tapping the chest during forced inspiration and forced expiration, as, by these means, tuberculous deposit may, in some cases, be discovered, even if overlapped by a portion of healthy or emphysematous lung.

In conducting the physical examination of incipient phthisis, the stethoscopist, however conversant with auscultatory phenomena, must never lose sight of the all-important principle of comparison. For example, feebleness of respiration we have seen to be a sign of commencing tuberculous deposit. True: but it is a sign also of pulmonary emphysema, bronchitis, and pleurisy with effusion; besides which, it is caused by pleurodynia, stricture of the larynx, partial obstruction of the bronchial tubes, or compression of these tubes by enlarged glands, tumors, &c.; and, lastly, the entire lungs may sometimes exhibit a naturally feeble murmur, without concomitant disease. How, then, are we to test the value of this sign as an indication of incipient phthisis? By careful comparison, not only with the corresponding sounds of the opposite side, but with those in the different regions of the same side; by investigating the other physical signs which may obtain, particularly the changes in inspiration and expiration; by percussion; and also by recollecting that

phthisis almost invariably commences in, and is at first confined to, the apices of the lungs; and of these, in general, the one is affected in a greater degree, or advances more rapidly, than the other.

The same principle of comparison holds good in the differential signification of many of the other signs of incipient phthisis, and, as such, claims throughout the examination the fullest importance, as being the only mode of avoiding error, and also of arriving at a correct diagnosis.

[To be continued.]

CICERO.

GRATUITOUS PRACTICE.

PERHAPS in no country in the world is medical assistance given to so large an extent without fee or reward as in England; and this is not the act of government, or a matter of state policy, but due to the spontaneous exertions of individuals. The instinctive attempt to supply the deficiencies of individual powers by combination has of course led us in this, as in most other things, to form societies for effecting the purposes of charity in a systematic, efficient, and economical manner; but these associations are voluntary, not compulsory; private, not public. Their magnitude and the wealth which they have gradually accumulated, has often given to them a public character, and their utility has often given them acknowledged claims to public assistance; but more often a far different effect has ensued, and the state which had no share in their foundation, has been urged to regulate their government, and administer, if not appropriate, their finances. Their wealth having become great, and their utility extensive, the *distribution of their benefits* profuse,

they have been first thankfully recognised as public blessings, and then looked upon as public property. The danger of spoliation, indeed, is in proportion to the degree of previous veneration; and the latter may with confidence be looked for when the former is at its height. Societies, like individuals, when they heap up riches, cannot tell who shall gather them.

Two classes of persons concur, from very different motives, in hastening this process. The one consists of men whose active benevolence and quick intelligence point out to them the vast good of which such powerful institutions seem capable, if placed under the most efficient possible management. A warm temperament, a conscientious industry, and a benevolence which has become expansive and habitual, leads such men to conceive gigantic plans of improvement, and fearlessly to undertake them. The indifference of placemen offends the best feelings of their nature, and they labour assiduously to remove, as the peculiar defects of their favourite institution, those evils which are common to the species. But the lever once applied, however tenderly and judiciously, to any part of a social edifice, is liable to be handled by the unskilful and the violent; and the force intended for raising and rectifying a part, is apt to be increased to the rending, if not the overthrow, of the whole.

The other class who conduce no less to the result above mentioned, are those who are opposed to all change, who, seeing a great deal of good effected, are unwilling to admit the propriety of attempting to do more. To them all novelty is dangerous, all projects are chimerical. An unmeaning resistance to all remonstrance however temperate, and all change however judicious, is apt to tempt disinterested reformers to alliances with those of the baser sort; similar allies are required in self-

defence, good motives are gradually merged in the desire for victory, and general confusion results.

We put out of the question those low motives which by the vulgar will always be mainly attributed to the two parties, believing most firmly that a malicious desire to overthrow what is good, and a selfish intention to preserve what is bad, do not actuate the principals on either side. The perversion of noble motives and generous aims have prompted most of the actors in political dramas, whether tragedies or farces. Satan, himself a fallen angel, tempts frequently through the noblest qualities.

But the ethical view of the subject must in our pages give way to the practical. The solemn introduction to the business of Boards and Committees, which the piety of the founders has appointed in most of our hospitals, is habitually neglected by many, and apt to be forgotten by all; but for truth of description and force of satire, Crabbe's clever description of the board-room and its *habitués* is worth occasional perusal.

It is undeniably the duty of a government to provide for the medical relief of the indigent, as well as for their sustenance and shelter; and we may moreover admit that it is the duty of government to purchase that relief on the cheapest terms that are consistent with goodness of quality. There is no more reason for paying too high a price for this, than for food, clothing, or lodging. There can be no "fancy fees" in such cases.

The duty, on the other hand, of individuals is, we conceive, not only to contribute that compulsory tax which is exacted under pains and penalties, to provide for the indigent a resource against absolute starvation—that mere antiseptic which is essential to prevent the whole body politic being poisoned by its own partial corruptions, but also

to do the work of charity actively and voluntarily in their own neighbourhood; not only to pay a poor-rate on compulsion, but to assess themselves for the good of their neighbours; not only to provide the workhouse and the Union doctor for the sick *pauper*, lest he "prove his right of settlement by falling sick of infectious fever," but to maintain hospitals for the sick *poor*. Happily this duty is very generally recognised, though the fiercest disputes are waged as to the manner of doing it. It is the duty of the state to provide for the *pauper*, and of individuals to strive that there be no *paupers*. This seems a somewhat large exaction, and it is; yet only those who strive to comply with it are fulfilling their social duties. Like all efforts, however, made from worthy and unselfish motives, it has a rich reward—a reward reaped, it may be, by those who never recognise the connection as cause and effect between it and the duty, but which may be seen in some degree by those who look for it with the eye of wisdom.

The metropolitan hospitals, and most others which have been founded and supported by private benevolence, are served by a medical staff whose services are gratuitous, and the appointments are sought by men of the highest promise, and frequently retained after the most brilliant success. The appointment to a hospital implies the putting forward a claim to a high place in public estimation, and a willingness to wait and to work until that claim shall be recognised. The duty is done in complete publicity, under the eye of governors, pupils, and fellow-practitioners, and is submitted to the severest scrutiny of which it is capable. This publicity, which, to a Frenchman, would be an attraction, is to nearly all Englishmen a mortification of the flesh. How few of our countrymen can make

a decent speech in public, how few even a decent bow; and when we find a man who can do either particularly well, we are apt to suspect that he enjoys the distinction at the expense of some more sterling qualities, or more solid acquirements. This is not mere envy; it is national instinct, often wrong, no doubt, but right in the main.

In calling appointments to public hospitals gratuitous, we have not forgotten the fees from pupils; but these are obtained under a still severer test: the dislike of his colleagues, who suffer from his unpopularity, must be a severe visitation for an incapable man. It may be remarked, that all these guarantees for efficiency, whatever they may be worth, are most secured by the elections being much influenced by the medical governors of an hospital. No doubt the medical interest, like any other, may take a selfish turn, and require wholesome correction from without; but, on the whole, the high character of medical men as a body will be best supported by the suffrages of their professional brethren; this will put them above degrading appeals to the public, where the public can only be right by accident.

Now it must be evident that a very different class of practitioners is raised up and supported by hospitals, where adult education is actively going on, from that fostered by union workhouses. This is wholly irrespective of personal respectability, and of relative efficiency, which may be possessed by individuals amongst each; the offices in our profession which are meanest to the common eye are ennobled by rectitude of purpose and of character. From hospitals gratuitously attended the easy and affluent classes are supplied with men who bring to ample opportunities of observation a long continued course of study. Their ambition is a proof of earnestness; their success of capacity;

their popularity of their being appreciated. The evils which ever attend a state of highly wrought refinement are by these men viewed *en masse*; and their palliatives (for, alas! there are but few cures which the victims will accept), are studied attentively, and applied with all the benefits of extensive experience. The rich are taught that their luxuries are the medicines of the poor, and that wisely it has been said, "It is not for kings to drink wine, nor for princes strong drink." "Give strong drink to him that is ready to perish, and wine unto those that be of heavy hearts." That physician ill performs his mission who neglects to be the exponent to the rich of the wants of the poor; his habitual contemplation of men of all ranks in a state of helplessness and selfishness should not increase his power without enlarging his charity, and deepening his responsibility.

Much has been said of the disproportion between the opportunities which hospital appointments afford for information, and the results which have been thence secured to science. Much of this is no doubt true, and is in course of improvement; but surely no reflecting or even observing man can consider what has already been obtained from hospital physicians and surgeons as small compared with that from other sources. The system of registration, indeed, now so obviously expedient, has been neglected by all parties; but it may fairly be asked, whether the naval and military services, with their advantages of centralization and discipline, have produced more men of eminence, or more works of utility, than the civil hospital appointments.

With the most sincere desire to see the general practitioner well educated, well esteemed, and well paid, we are convinced that the habit of earning

name and fame, during a long period of gratuitous practice, produces some advantages which would be forfeited on a different system. It is always painful to see the payment for medical attendance made the subject of bargain and contract, still more of litigation; the latter shocks us less on account of the loss to which our brother has been exposed, than from regret that his dignity should have been compromised by the occurrence. There must have been a grievous interruption of the honourable relation which ought to subsist between a patient and his medical adviser, before matters could have reached so far; and perhaps litigation is never advisable except in the case of fraudulent executors. It is much, certainly, to have established by legal process the right of remuneration for medical attendance, without proving the delivery of medicines to the required amount; it will forward the abolition of payments by medicine, so much to be desired; but we should beware how we bring into the market the higher and more subtle implements of our art, such as knowledge, skill, and moral character. The saving of the baggage is sometimes considered as glorious as a victory; but this can only be when an engagement has been unavoidable. When the doctor gives battle for his fees, his victory seldom secures a triumph.

No doubt gratuitous practice will recede as civilization advances. There are evils and there are virtues appertaining to barbarism; mendicancy and hospitality are of this kind. The caravanserai and the fountain on the way side bring rest and refreshment to the traveller, and call forth blessings on the pious founder; but however picturesque and welcome in the primitive East, they are gladly exchanged by the returning Englishman

for the house cistern and the hotel, though the one exposes him to the gentle extortions of a polite waiter, and the other to arrest for arrears of water rates. While there are poor in the land, however, the philanthropist and man of science need not lack welcome opportunities of practising gratuitously; nor, it may be remarked, need the legislator be alarmed lest able men be not found willing to undertake the drudgery of attending the poor.

COMPOUND DISLOCATION OF THE FIRST UPON THE SECOND PHALANX OF THE THUMB—

REDUCTION IMPOSSIBLE—RESECTION OF THE HEAD OF THE FIRST PHALANX—CURE.

By G. W. NORRIS, M.D.

Surgeon to the Pennsylvania Hospital.

NEILL LARKIN, a stout drayman, ætat. 28, while engaged in unhitching his horse, had the end of his left thumb accidentally entangled in a link of the drawing chain, when the horse starting suddenly, dragged him some distance, and produced the accident just mentioned. He was brought to the hospital late in the evening of February 17th, a couple of hours after its occurrence, when strong and well-directed efforts were unsuccessfully made to reduce it, the clove hitch being attached to the extremity, after a first failure with the hand alone. On the following morning I found the head of the first phalanx protruding considerably inwards through a wound which embraced more than one-half of the circumference of the finger; another effort at reduction was now attempted by bending the luxated phalanx and endeavouring to push its projecting head over that of the adjoining bone, but failing in this, I determined to remove the protruding extremity of the bone, which was at once done with the metacarpal saw, to the extent of three or four lines, after which the parts were easily replaced. The edges of the wound were then drawn together with strips of narrow adhesive plaster, and the part covered with dry lint, the hand and fore-arm being secured upon a splint. After the third day, the dressings were daily made, the part being only covered with simple ointment. No unpleasant symptoms followed.

March 23d.—Wound entirely closed; on the 26th he was discharged, and on the 13th

of April he called at the hospital, at which time he had good use of the thumb with some motion at the point of injury.

The difficulty of reduction in cases of simple luxations of the phalangeal articulations, even when the patient is seen soon after the accident has occurred, is well known; and the same difficulty exists in reducing and retaining in place compound injuries of this class. So hard is the reduction to effect, that it is asserted upon the authority of Bromfield, that the extending force has been increased to such a degree as to tear off the second joint in efforts to reduce the first. In compound luxations of the thumb, when found irreducible upon the application of a moderate degree of force, I believe the best practice to be that which was pursued in Larkin's case, viz., to saw off the end of the projecting bone. If the wound be large, and this be not done, observation shows that, even when the part can be reduced, the dislocated end will in the majority of cases become displaced, as the inflammation necessarily following it prevents the application of a sufficient degree of force by bandages and splints, to retain it in its natural position. One case of this kind I have myself witnessed, and another instance which occurred in Guy's Hospital has recently been published, in which, although the phalanx was easily reduced immediately after the accident, so much inflammation and constitutional disturbance occurred, as to make it necessary to remove the splints and other dressings which had been applied, and resort to cataplasms; the patient being ultimately cured, after entire loss of the first, and exfoliation of the extremity of the second phalanx. Resection of the phalangeal extremity is the practice recommended by Sir A. Cooper, in compound dislocations of these parts, when difficulty is experienced in their reduction, and has often been done with good success. Gooch states that he sawed off the head of the second bone of the thumb, and that a new joint afterwards formed. In two instances, where the head of the metacarpal bone of the thumb was dislocated towards the palm, accompanied with wound, and reduction was difficult, the protruding parts were successfully sawn off by Mr. Evans. Robe, Wardrop, and Roux, have all been successful in like cases. The bad effects resulting from those injuries where the head of the bone is replaced, and which seem to be at least in part owing to the force necessarily made use of, and the state of tension afterwards kept up in the surrounding soft parts, by its return, has been often noticed. An instance came under my care, in which high inflammation and tetanus ensued upon the injury where this practice was pursued; and Mr. S. Cooper reduced a case at the

North London Hospital, which was followed by severe inflammation, terminating in death, a week after the accident.—*American Journal*.

ON THE PREPARATION OF MURIATIC ACID.

BY HEUMANN.

THE preparation of pure muriatic acid is one of the easiest operations, provided that we follow Gregory,* and employ one atom by weight of chloride of sodium, and two of sulphuric acid. The latter must be diluted with water enough to bring down the specific gravity to 1.6, for which purpose from nine to twelve ounces of water will be required to 2½lbs. of fuming Nordhausen acid. This proportion was recommended by Dr. Wittstein† as the best for effecting the entire decomposition of the chloride of sodium. Moreover, the salt must be perfectly free from iron, and the sulphuric acid from arsenic.

A common glass alembic serves as the vessel for the development of the muriatic acid gas; and a glass tube, twice bent at right angles, conducts it into a receiver containing pure water, which must constantly be kept as cold as possible. By a proper management of the fire, the development and absorption of the muriatic acid gas go on easily and uninterruptedly.

The muriatic acid thus obtained varies in specific gravity according to the quantity of water employed. It is perfectly colourless, and is free from sulphuric acid, from sulphurous acid, from chlorine, iron, and arsenic.

All sulphuric acid employed in pharmacy must necessarily be tested for arsenic, as there is English sulphuric acid now in the market which abounds in this pernicious contamination. I lately examined an acid of this kind from a manufactory on the Rhine, which, when tested with sulphuretted hydrogen gas, afforded 0.7 of a grain of sulphuretted arsenic in an ounce, equal to 0.42622 of a grain of arsenic. If an acid of this kind is employed, the whole quantity of arsenic is found in the muriatic acid, not a trace of it being discoverable in the bisulphate of soda which remains.

This is the source of the arsenic so frequently found in the muriatic acid of commerce, which renders it totally unfit for pharmaceutical use. The method of detecting arsenic in muriatic acid is well known.—*Annals of Chymistry*.

† Buchner's *Repert.* Band xiii.

EMPHYEMA TERMINATING FAVOURABLY BY SPONTANEOUS OPENING.

THE subject of this case was a man of a stout, robust appearance, who presented the usual symptoms of acute inflammatory fever, accompanied with cough, dyspnoea, and a fixed pain near to the inferior border of the left scapula, extending across the posterior surface of the chest.

On the 3d of October, 1838, while engaged in raising a heavy piece of timber, "he felt something give a crack" in the foregoing position, which, however, did not prevent him continuing his employment during the entire day; but on the following day, while rowing a boat, he became chilly and squeamish, and was forced to bed, when the above symptoms made their appearance.

Mr. S. saw him on the 5th of October, and took blood to syncope, and prescribed an antimonial saline mixture, some powders containing calomel and antimonial powder, and applied a sinapism to the painful part.

On the following day, there being no improvement, the blood-letting was repeated, a large blister was applied, and the medicine continued. The sputa, which now became more copious, from its rusty character, and the ordinary stethoscopic indications, enabled me to consider the inflammatory action to have extended to the substance of the lung. The usual antiphlogistic measures were continued; blisters repeated from time to time; and in the course of a few days, the acute febrile symptoms subsided; but there still remained the fixed pain near the scapula, frequent cough, copious expectoration, and a total inability to lie upon the right side, any attempt at which greatly aggravated the cough and dyspnoea. Very little benefit was derived from the treatment adopted; colliquative perspirations were superadded, to ameliorate which, mineral acid and quinine were had recourse to.

Towards the end of December debility and emaciation had advanced progressively, and a fulness was observed over the left side of the chest, although no difference in its capacity was found upon measurement; percussion on the part elicited a dull sound; and the respiratory murmur was very faint, although audible over the subclavian region; and a few days after, a soft tumor appeared on the fifth intercostal space, an inch below, and to the outside of the left nipple.

The next day Mr. S. found that the surface of the tumor had ulcerated, and the patient lay bathed in purulent matter, the bed and clothes being fully saturated with it. The purulent matter continued to flow daily from the aperture, and some came afterwards by the mouth. The patient was after-

wards kept comfortable by evacuating the purulent matter night and morning to the extent of a pint, which was facilitated by turning him to the left side, and requesting a full inspiration and a cough to be made, when a soft pledget with a quantity of tow and a bandage was applied.

The cough and dyspnoea were now greatly relieved; a generous diet, with porter, together with the acid and quinine, were prescribed, under which he gradually regained so much strength as allowed him to go out of the doors by March 1839; and henceforward he continued still so weakly as only to be able to walk a very short distance, while the purulent matter was continued to be evacuated night and morning, in nearly the same quantities as at first, by removing the bandages, &c. until three weeks ago, when blood appeared instead of purulent matter, and the wound thereafter closed, leaving a flattened, thimble-like cavity, into which the point of the finger could be introduced; and he has since progressed in strength.

Upon examination, the movements of both sides of the chest are equable and the respiratory murmur natural, as also the sound elicited by percussion.

The successful result of this case may, perhaps, be regarded as a support to the practice generally adopted, of gradually evacuating such collections, as it is very probable that only as much purulent matter flowed in the first instances as reduced it to the level of the aperture.—*Edinburgh Medical and Surgical Journal.*

LECTURES ON ANIMAL CHEMISTRY.

To the Editor of the Medical Gazette.

SIR,

HAVING lately heard from some members of the Apothecaries' Company that a course of lectures are being delivered by Professor Brande on Animal Chemistry, it appears to me, that if the lectures delivered to the members only were extended to the licentiates, I am sure they would gladly avail themselves of the privilege of attending; and as the lectures delivered at the College of Physicians are open to the licentiates of its body, and the same at the College of Surgeons, I do hope that the Society of Apothecaries will confer the same boon on its licentiates. Trusting that this appeal may not have been made in vain, and as an advocate for whatever is calculated to advance professional knowledge, I am sure you will reciprocate that wish.—I remain, sir,

Your obedient servant,

AN OLD LICENTIATE.

London, May 24, 1843.

**SOCIETY FOR RELIEF OF
WIDOWS AND ORPHANS OF
MEDICAL MEN IN LONDON
AND ITS VICINITY.**

THE annual dinner of the above Society, which was postponed in consequence of the lamented death of the Duke of Sussex, the Patron, is now appointed to take place on Saturday, the 3d of June. H. R. H. the Duke of Cambridge has signified to the Stewards his intention to preside on the occasion.

MR. TYRRELL.

WE regret very much to record the sudden death of Mr. Tyrrell, of St. Thomas's Hospital, which took place on the 23d inst. in consequence, it is said, of disease of the heart.

BOOKS RECEIVED.

A Practical Treatise on the Diseases of the Testis, and of the Spermatic Cord and Scrotum; with Illustrations. By T. B. Curling, Lecturer on Surgery, &c.

Austria: its Literary, Scientific, and Medical Institutions, &c. &c. By W. R. Wilde, M.R.I.A. &c.

The Plea of Humanity and Common Sense against Surgical Operations for the Cure of Impediments of Speech. By James Wright, Esq.

The Educational and Subsidiary Provisions of the Birmingham Royal School of Medicine and Surgery, set forth in a Letter to the Rev. Dr. Wilson Warneford, LL.D. The whole being intended to shew the importance and practicability of applying the means actually possessed to some arrangement for providing *Collegiately* for the Board, Lodging, and Tutelary Care of its Pupils during their Residence at Birmingham for the Purposes of Study. By the Rev. Vaughan Thomas, B.D. Vicar of Stoneleigh, Warwickshire.

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE XXVIII.

On the application of the forceps.

THE midwifery forceps was invented and perfected by the Chamberlens about the middle of the 17th century, but it was first described by Chapman in 1733. "Almost every candidate for celebrity," observes Mr. Streeter, "has thought it necessary to modify the instrument; Dr. Churchill has given figures of more than fifty varieties." In the last half of the 18th century, or a few years earlier, the forceps had been altered by Menard, Gregoire, Rathlaw, Smellie, Levret, Bing, Burton, De Wind, Pugh, Wallis Johnson, Fried, Leake, Petit, Van De Lear, Contouly, Pean, Sleurs, Orme, Lowder, Young, Aitken, Mayer, Starke, Saxtorph, Osborn, Denman, Hamilton, Highton, J. Clarke, and Thynne. [Müller's plates were here exhibited, in which many of these instruments have been represented.] Dr. William Hunter appears to have been almost the only distinguished accoucheur, who lived during that period, who considered it unnecessary to modify the shape of the forceps. The instrument has undergone many changes during the present century, but that form which I prefer greatly above all others is the Chamberlen forceps, with the lock and wooden handles of Smellie—in fact, Denman's short forceps covered with leather; because it is easily applied, takes a fast hold of the head, and it may be employed with less risk to the mother, than the forceps of Drs. Hopkins, David Davis,

Naegele, Siebold, and others. But in truth I attach comparatively little importance to the shape and dimensions of the forceps you use, and think it nearly a matter of indifference whether it has a pivot lock or Smellie's lock, and whether the handles consist of wood or metal, provided the case will justify the use of the forceps where it is had recourse to, and you know the principles which ought invariably to guide you in its employment. The observations which have been made upon the forceps during the last 110 years, have proved that it is not adapted to cases of difficult labour, in which the os uteri, vagina, and other soft parts, are in a rigid, swollen, inflamed, and undilatable state; where the umbilical cord is unusually short, or is twisted once or several times around the neck and trunk of the child, where the child is hydrocephalic, or the head greatly exceeds the natural size, and where the pelvis is obstructed by tumors, or much distorted by rickets or malacosteon. It is now admitted by all practitioners in this country that the forceps ought not to be employed where a great disproportion exists between the head of the child and pelvis from any cause. It is chiefly in cases of protracted and difficult labour, from feeble, irregular, or partial uterine action, from passions of the mind, original or accidental debility in the mother, and other constitutional causes which impair the energy of the brain, and nervous system of the uterus, that the forceps is used with advantage, and where, if any disproportion exists between the foetus and pelvis, it is only in a slight degree. The forceps is not applied because there is a great deficiency of space in the pelvis, a great want of due proportion between the head and pelvis, but because there is a want of power in the uterus to propel the child through it, the want of which power we endeavour to supply with the forceps. This is the only legitimate ground on which we can proceed in the application of the forceps, whether it be exhaustion,

convulsion, hæmorrhage, or whatever the circumstance may be which renders immediate delivery necessary to preserve the life of the mother and child. It is not for our own convenience, to spare ourselves the anxiety and fatigue of a protracted attendance upon any case of labour, to acquire skill and dexterity in the use of the forceps, that the instrument is to be applied, nor because it is in our power to do so, but in consequence of certain local and constitutional symptoms appearing in the parent, or because the child is in danger from the long-continued pressure, that we have recourse to artificial delivery. The gradual cessation of labour pains, and the descent of the head being arrested, are unquestionably the best indications we can have for the propriety of the interference of art. If the uterine contractions cease, and the head, swollen and compressed, becomes arrested or impacted in the pelvis, and there is exhaustion, fever, and disturbance of the brain, and we believe that the head of the child will not be expelled by the natural efforts, it is our duty to endeavour without delay to extract it with the forceps. To apply the instrument, when it is known with absolute certainty that the child is dead, would betray, to use the mildest expression, the highest degree of human insensibility and folly.

In a great proportion of cases they are first labours in which the forceps is required; which proves that the difficulty frequently depends on the soft parts. It is not from the duration of the process, so much as from the condition of the patient, that you are to judge of the necessity for interference. In some women, whose nervous energy is feeble, exhaustion, delirium, or some other unfavourable symptom, occurs before the labour has continued 24 hours; in others there is no unfavourable symptom witnessed, though it is greatly protracted beyond this period. In general it is a very good practical rule, and well calculated to prevent the rash and unwarrantable use of the forceps, "that the head of a child shall have rested six hours as low as the perineum, that is, in a situation which would allow of their application before the forceps are applied, though the pains should have ceased during that time." But there are exceptions to this rule, and cases occur of rapid exhaustion, or some accident takes place suddenly, in which it would be wrong to comply with it. The membranes must be ruptured, and the os uteri fully dilated, before the forceps can be safely applied. The head may not have wholly escaped from the uterus, but the greater part must have done so, to render it possible to use the forceps without great risk. *If the whole circumference of the os uteri can be felt, you must not think of the for-*

ceps, and the greatest care is required, though the posterior lip has gone up beyond the reach of the finger, if the anterior lip and cervix can be felt between the head and symphysis pubis. I have never met with a case in which the forceps was satisfactorily applied before the os uteri was fully dilated, and the head had descended so low that an ear could be felt. "Before the completion of the first stage of a labour," says Dr. Denman, "that is, before the os uteri be completely dilated and the membranes broken, the use of the forceps can never come into contemplation; because the difficulties before occurring may depend upon causes which do not require their use, or if required, they could not be applied with safety or propriety before those changes were made." In almost every case, "says Dr. Burns, "where the forceps are beneficial, the head has so far entered the pelvis as to have the ear corresponding to the inner surface of the pubes, and the cranial bones touching the perineum." "No case," observes Dr. Merriman, "is to be esteemed eligible for the application of the forceps until the ear of the child can be distinctly felt."

Smellie invented a pair of long forceps, which he sometimes used when he found the head of the child so much forward over the os pubis, by the unusual projection of the sacrum and lower lumbar vertebra, that he could not push the handles of the short forceps far enough back to include within the blades the bulky part of the head which lay over the pubes. To remedy this inconvenience he contrived a long pair, curved on one side and convex on the other; but these, he says, ought never to be used except when the head is small; for when the head is large, and the greater part of it remains above the brim, the parts of the woman may be inflamed and contused by the exertion of too much force. Where the vertex presents, but only an inconsiderable part of the head, resembling the small end of a sugar-loaf, is forced down into the pelvis, after a protracted labour, we may infer that the head is either too large, or the pelvis too narrow. In these cases, indeed, a long pair of forceps may take such firm hold, that with great force and the strong purchase the head will be delivered; but such violence is commonly fatal to the woman, by causing such an inflammation, and perhaps laceration, of the parts, as is attended with mortification. In order to disable young practitioners from running such risks, and to free myself from the temptation of using too much force, I have *always used and recommended* the forceps so short in the handles that they cannot be used with such violence as will endanger the woman's life, though the purchase of them

is sufficient to extract the head when one-half or two-thirds of it are equal to, or past, the upper or narrow part of the pelvis. Smellie was so fully aware of the danger of fetal contusion and laceration of the uterus and vagina necessarily incurred by the application of the long forceps, when the head of the child remained above the brim of the pelvis, that he did not venture to exhibit the instrument to the pupils of his class, from the dread that it would be misapplied; and it appears *as always used* and recommended the short forceps. Levret likewise invented a pair of long forceps, convex on one edge, and concave on the other, which have been extensively employed on the continent, especially in France and Germany, for the purpose of drawing the head of the child into the cavity of the pelvis when the brim is contracted. The common French midwifery forceps, represented in these figures, will give you some idea of the instrument recommended by Levret, though not precisely the same:—

1. The instrument closed.
2. A partial front view of one blade, to shew the curve and peg by which it is locked.

You will meet with two very great difficulties in attempting to apply the long forceps. The first is, that the head of the child always lies transversely, or diagonally, at the brim of the pelvis; so that if the blades of the instrument are passed up along its sides, which all admit they must be, one blade will be applied over the occiput, and the other over the forehead; and you can have no hold of the head in this way upon which you can depend. If you make the experiment upon a dead child, as I shall now do before you, you will at once be satisfied that the hold which the forceps has of the head is so insecure that it would be

impossible to overcome any considerable resistance with the blades thus applied to the forehead and occiput; over the sides of the head they give you a firm hold. And in actual practice, in all the cases where I have seen an attempt made to deliver with the blades of the long forceps applied over the forehead and occiput, the instrument has soon lost its hold, and has slipped off the head, where any considerable extracting force has been applied. But if the instrument should not slip, the compression of the occiput and forehead would increase the length of the short diameter of the head, which corresponds with the contracted conjugate diameter of the brim, and the result would be an increase of the disproportion between the head and pelvis; the size of the head would be increased in the wrong direction—in fact, where it is required to be lessened. If you look at this plate of Maygrier [exhibiting it], you will be convinced of the truth of this.

But besides, before the greater part of the head has passed through the brim of the pelvis, the os uteri is never sufficiently dilated to allow of the long forceps being applied without the greatest danger. “The delivery of a female with the forceps, when the os uteri is fully dilated,” observes Dr. Collins, “the soft parts relaxed, the head resting on the perineum, or nearly so, and the pelvis of sufficient size to permit the attendant to reach the ear with the finger, is so simple, that any individual with moderate experience may readily effect it. I have no hesitation in asserting, that to use it under other circumstances is not only an abuse of the instrument, but most hazardous to the patient. It is from being thoroughly convinced of these facts, by long and extensive observation, that I consider the forceps quite inapplicable when the head becomes fixed in the pelvis, and that the ear cannot be reached by the finger, except by violence, in consequence of disproportion existing between the head and pelvis, either owing to the former being unusually large, or the latter under size; in most instances measuring little more than three inches from pubes to sacrum, and in others less than this. When we consider that the blades of the smallest sized forceps used in Britain, even when completely closed, measure from $3\frac{1}{4}$ th inches to $3\frac{1}{2}$ th, it is clear that were the bones of the pelvis denuded of their soft parts there would not be space to admit of their application. The French forceps measure, when closed, from blade to blade, on the upper side $2\frac{1}{2}$ inches, and are about $\frac{1}{4}$ th wider on the opposite side, meeting at the point of the blades to within $\frac{1}{4}$ th of an inch. Were we even to overlook altogether the safety of the mother, where the child's head measures $13\frac{1}{2}$, $14\frac{1}{2}$, or 15 inches in circumference, is so compressed,

as it must be when the instrument is closed, there can scarcely be a hope of life. Of course, where the pelvis is roomy, this compression of the head, so as to close the forceps, is unnecessary, and in such cases the child is uninjured. How is it possible, with the forceps, to drag a child through a pelvis where there is not space, except by force, to introduce (as is commonly said) a straw, or where the smallest flexible catheter cannot, in some instances, be passed into the bladder? The results I have witnessed from such practice were most distressing: in some, the neck of the bladder, or urethra, either lacerated, or the injury by pressure from the forceps so great as to produce sloughing and consequent incontinence of urine; in others, the recto-vaginal septum destroyed; either of which renders the sufferer miserable for life; and in two cases, where the mouth of the womb was imperfectly dilated, so much injury inflicted on this part as to terminate in death. Such melancholy consequences strongly show the necessity of having recourse to the forceps with great caution, so as to avoid the abuse of an instrument which, when judiciously applied, is occasionally most beneficial. Almost all the unfavourable results may be prevented by using the instrument only when necessary for the safety of the patient, at the same time attending to the circumstances already stated, which are dwelt upon by many of our best writers on this subject when treating of the nature of the case in which it is eligible." The accuracy of these remarks is fully confirmed by all the forceps cases which have come under my observation, and which exceed 60 in number. Four of the mothers whose cases (55) are related in the First Report of my Clinical Midwifery, died from the rash and inconsiderate use of the forceps; seven had the perineum more or less injured; one the recto-vaginal septum torn; five were left with cicatrices of the vagina after sloughing; and one with an incurable vesico-vaginal fistula. In none did any benefit result from the instrument before the greater part of the head of the child had passed through the brim of the pelvis, and the orifice of the uterus was fully dilated. In one case only was the forceps advantageous, when the blades were applied and locked with great difficulty, and great force required to extract the head of the child. Only seventeen of the children were born alive and lived. In protracted labours, when the head has made no sensible advance for hours, I repeat once more, and becomes compressed, the scalp puffy and swollen, the vagina dry, hot, and tender, the discharges offensive, and when the bladder cannot be emptied without the catheter, it is dangerous *to trust longer to the natural efforts. If, along with these symptoms, there is tender-*

ness of the abdomen, fever, incoherence, restlessness, and exhaustion, delaying long to deliver is invariably followed by the most injurious consequences. But if the os uteri is not fully dilated, and the greater part of the head has not passed through the brim, the forceps cannot be employed with advantage.

Most of the authors who have recommended the long forceps to be employed have been fully aware of the danger of the instrument, and the necessity for extreme caution in its use. "Sometimes it is useful," says Dr. Hamilton, "to employ a lengthened pair of forceps: but as in operating with that instrument the parts of the woman in contact with its blades must inevitably be pressed upon in a degree proportionate to the length of the instrument, the extent of its motion, or, in other words, to the force of the operator working with it, it is a very hazardous expedient in the hands of the inexperienced." When Dr. Hamilton was in London, twelve or thirteen years ago, the use of the long forceps was one of the subjects of conversation which I had with him, and I was astonished when he informed me that he had entirely for some time laid aside the short forceps. On further inquiry, however, it appeared that in no case did he ever use the long forceps until an ear could be felt; thus admitting that he never employed the long forceps where it was not possible to deliver with the short forceps, and to derive all the advantage that could be obtained from such means with much less risk. If I recollect right, Dr. Hamilton stated on that occasion that he had used the forceps, long and short, only about forty times in the whole course of his life. In respect to the frequency with which he employed the forceps, his practice probably coincided with that of Dr. Joseph Clarke, who says, in his valuable Report of the Dublin Lying-in Hospital, "Cases of convulsion excepted, I have rarely had reason to be well pleased with the effects of extracting instruments, and not unfrequently have I had much reason to deprecate their evil consequences. Whenever labour is protracted to a dangerous length, by unusual resistance, there is nothing but mischief to be expected from their application, but when the expelling powers are impaired by debilitating diseases, the interposition of an artificial extracting power is more rational and justifiable. Let it be remembered that in the hospital such means were employed in one of 728 cases, and in private practice it is so long since I have had occasion to use, or even to think of using them, that I am persuaded a fair opportunity of applying forceps with good effect will not occur to a rational practitioner in one of 1000 cases."

Where the child is dead, where a great disproportion exists between its head and the

pelvis from any cause, and the os uteri is imperfectly dilated and the parts swollen and rigid, and an ear cannot be felt, and circumstances occur demanding immediate delivery, recourse must be had to the perforator, and not to the forceps. You will never, I hope, think of applying the forceps in a secret or clandestine manner. If you were so thoughtless as to attempt to do this, you would not succeed without the attempt being discovered, and your rashness and imprudence exposed. But you might introduce the vectis or lever over the head without the patient or nurse being aware of the fact; and this is one of the many strong objections which I have to the instrument, of which the following figures are representations.

It has a joint to render it more portable, and some practitioners carry it in their pocket to every case of labour they attend, and make use of it without apprising the patient. Such conduct, I look upon, with Dr. Collins, "as unjustifiable in the extreme, and am happy to think it is the practice of those only who have little character to lose."

In all cases of protracted and difficult labour in which you consider it requisite to employ the forceps, or to perform the operation of craniotomy, or any other operation in midwifery, you will promote your own peace of mind and professional interests, and the welfare of your patients, by previously consulting another experienced practitioner, whenever it is practicable to do so. When exhausted with fatigue and watching, we are not in a condition to form a sound opinion respecting the necessity for the interference of art, and it is agreeable in all cases of difficulty and danger to have the responsibility divided by

a consultation, and mistakes in practice prevented by every means in our power. After all the circumstances of the case have been deliberately considered in consultation, and the necessity for the employment of the forceps satisfactorily proved to exist, it is right, before proceeding to apply the blades, to state to the husband and relations, and even to the patient herself, if she is in a condition to comprehend, the reasons why you have resolved to trust no longer to the efforts of nature, and even to explain to her what you are going to do. All women know well the danger they incur when delivered with instruments, and dread being cut or torn by them. This fear is often removed, and the entire consent of the patient obtained, by shewing to her one or both of the blades unlocked of the short forceps, covered with soft leather, which makes it not only in appearance but in reality a safer instrument than when the steel blades are bare.

Having obtained the patient's consent to the application of the forceps, and a promise to endure the pain with as much steadiness and resolution as possible, let her lie on the left side, with the nates close to the edge of the bed, and the knees bent and drawn up towards the abdomen. Let the nurse support the right thigh, and keep the knees separate, and let the patient take hold of the hands of a steady person before her, who can control her feelings on the occasion. Ascertain by passing the catheter that the bladder is empty before you proceed further. Then take a blade of the forceps by the handle in your left hand, and pass all your fingers of your right hand in a conical form covered with lard slowly into the orifice of the vagina, and if it is a first child, and the parts are contracted, gently dilate them, and press back the perineum. When this has been sufficiently effected, pass the four fingers of the right hand forward into the vagina deeply, as far indeed as the root of the thumb, between the head of the child and front of the pelvis. Dr. Denman says, "the forefinger of the right hand should be passed between the ossa pubis and the head of the child to the ear." I would recommend you to pass all the fingers completely over the side of the head, so as to feel the ear, and to determine positively to which side of the pelvis the occiput is directed. If you introduce only one finger, or all the fingers, in the manner represented in these plates of M. Moreau and Dr. D. Davis [exhibiting them], you cannot possibly know what the actual position of the head is before you introduce the blades, and may turn the head in the wrong direction. I believe it is possible in every case, and I consider it necessary, to ascertain exactly the position of the head before passing the first blade of the

forceps. If the head is so firmly impacted that you cannot pass the fingers not only to the ear and side of the head, behind the front of the pelvis, but completely around the whole head, you will do nothing but mischief with the forceps. Pass, then, the four fingers of the right hand completely over the side of the head and ear behind the symphysis pubis, for in a vast proportion of cases an ear is felt in this situation, and not at either side of the pelvis, and when you have determined the position of the head, the point of the blade in the left hand is to be slowly and cautiously, without any force, slid up between the head and your fingers, till the blade is closely applied over the side of the head, and the lock is about an inch and a half from the fore part of the orifice of the vagina. When you begin to pass the blade, you see in the phantom that its handle is directed backward to the perineum, but as its point slides along the convex surface of the head, the handle is gradually brought forward towards the pubes. You may either have the first blade held firmly in its situation by an assistant, or you may keep it in its place with the ring and little finger of your left hand, while you are engaged in passing the second blade over the opposite side of the head, which is usually attended with greater difficulty than the first. I prefer entrusting the first blade to another person, while I am engaged in passing up the four fingers of my left hand as far as possible over the side of the head in the hollow of the sacrum, and conducting the second blade with my right hand over it. When this has been done in a satisfactory manner, the blades lock with the greatest ease—they come together almost spontaneously. But where the blades have not been properly applied to the opposite and corresponding sides of the head, but one is toward the forehead and another to the side of the occiput, the extremities of the handles are in different directions, and the blades cannot be made to lock without drawing the handles forcibly together. Where this happens, the best plan is to withdraw one or both blades, and to reintroduce them in such a manner that they shall cover exactly the opposite sides of the head.

When the blades are thus applied, take care that no part of the mother is included in the lock, before you begin to extract. When a pain comes on grasp the handles of the instrument in your right hand, place your hand over or above the handles, and bring them slowly forward towards the symphysis pubis, and after keeping them there for an instant move them backward slowly and steadily towards the perineum, exerting upon the head a slight degree of extracting force. This action must be repeated, and at the same time you should en-

deavour to turn the face round into the hollow of the sacrum. When the labour pain goes off, take the pressure of the blades of the forceps from the head, and merely keep the handles together to prevent the instrument from slipping, and renew the traction with the same caution, but with a little more force. Until the head is brought so low as to press upon the perineum and distend it, the extracting force should be directed backward, but when the head has advanced, and the perineum becomes very prominent, the action should be directed more forward toward the pubes. In some cases, by the exertion of very little extracting force, and in a very short time, sometimes even during a single pain, the head is brought down so as to distend the perineum, the ears are placed to the sides of the pelvis, and the face is in the hollow of the sacrum, and farther advanced than is represented in the following figure.

In other cases a considerable period elapses, and much force is required before the head can be brought into this situation, and occasionally we do not succeed in bringing it so low after exerting all the force we dare employ. When the head begins to advance through the os externum, and the perineum is greatly distended, you must change the direction in which you extract. Now place your hand under or below the handles of the forceps, and gently draw the head during the pains forward to the symphysis pubis away from the perineum, and move it gently from side to side. It is necessary to observe the condition of the perineum while the head is passing, and to regulate every movement with the forceps, by seeing what degree of pressure it is able to bear, and to support it with the left hand most carefully when it is

rigid : imitate nature, by allowing the head to press against it for a considerable time, without exerting any considerable extracting force. The utmost circumspection is required in this part of the operation, and in some cases, where you see the perineum beginning to tear in spite of all your care, the best plan is to remove the blades of the forceps, and leave the expulsion of the head to the natural efforts.

I shall read to you Dr. Denman's account of the application and action of the forceps, which is remarkably full, plain, and easy to be understood, for the purpose of supplying any omissions or deficiencies in the previous description, and to make you more familiar with the subject.

“ The first part of the operation consists in passing the fore-finger of the right hand behind the ossa pubis and the head of the child to the ear; then, taking the part of the forceps to be first introduced by the handle in the left hand, the point of the blade is to be slowly conducted between the head of the child and the finger till the instrument touches the ear : there can be no difficulty or hazard in carrying the instrument thus far, because it will be guided, and in some measure shielded, by the finger. But the farther introduction must be made with a slow semi-rotatory motion, keeping the point of the blade not rigidly, yet closely, to the head of the child, by raising the handle toward the pubes. In this manner the blade must be carried gently along the head till the lock reaches the external parts near the anterior angle of the pudendum. The point of the blade, while introducing, sometimes hitches upon the ear of the child, and it then requires a little elevation. But when it has passed the ear, and is beyond the guidance of the finger, should there be any check to the introduction either of this or the other blade, it should be withdrawn a little, to give us an opportunity of discovering the cause of the obstacle, which we must never strive to overcome by violence, though we must proceed with firmness. When the first blade is properly introduced, it must be held steadily in its place by pressing the handle towards the pubes, and it will be a guide in the introduction and application of the second blade. Let the second blade be introduced in this manner. Keep the blade first introduced in its place with the two lesser fingers of the left hand, and carry the fore-finger of the same hand between the perineum and head of the child, as high as you can reach. Then take the second blade of the forceps by the handle in the right hand, and, conveying the point between the finger placed within the perineum and the head of the child, conduct the instrument, with the precautions before mentioned, so far that the lock shall touch the interior part

of the perineum, or even press it a little backwards. In order to fix the two blades thus introduced, that which was placed towards the pubes must be slowly withdrawn and carried so far backwards that it can be locked with the second blade retained in its first position ; and care must be taken that nothing be entangled in the lock by passing the finger round it. When the forceps are locked, it will be found convenient to tie the handles together with sufficient firmness to prevent them from sliding or changing their position when they are not held in the hand, but not in such a manner as to increase the compression upon the head of the child. Should the blades of the forceps be introduced so as not to be opposite each other, they could not be locked ; or if, when applied, the handles should come close together, or be at a great distance from each other, they would probably slip, or there would be a failure of some kind in the operation, as the bulk of the head would not be included, or they would be fixed on some improper part of the head, though allowance is to be made for the difference in the size of the heads of children. But if a case be proper for the forceps, if they be well applied, and we were to act slowly with them, there would not be much risk of failure or disappointment. The difficulty of applying the forceps is most frequently occasioned by attempting to apply them too soon, or by passing them in a wrong direction, or by entangling the soft parts of the mother between the instrument and the head of the child, against all which accidents we are to be on our guard.

“ When the forceps are first locked, they are placed backwards, with the lock close to, or just within, the internal surface of the perineum ; and they can have no support backwards, except the little which is afforded by the soft parts. The first action with them should therefore be made by bringing the handles, grasped firmly in one or both hands, to prevent the instrument from playing upon the head of the child, slowly towards the pubes till they come to a full rest. Having waited a short interval with them in that situation, the handles must be carried back in the same slow but steady manner to the perineum, exerting, as they are carried in the different situations, a certain degree of extracting force ; and after waiting another interval, they are again to be carried towards the pubes, according to the direction of the handles. Throughout the operation, especially the first part, the action of that blade of the forceps originally applied towards the pubes must be stronger and more extensive than the action with the other blade, this having no fulcrum to support it, and chiefly answering the purpose of regulating the action of the other blade. If there were any

labour pains when the operation was begun, or should they come on in the course of it, the forceps should only be acted with during the continuance of the pains; the intention being not only to supply the want or insufficiency of the pains, but to follow them, and imitate also the manner in which they return. By a few repetitions of this alternate action and rest before described, we shall soon be sensible of the descent of the head; and it will be proper to examine very frequently, to know the progress made, that we may not use more force than needful, nor go on with more haste than may be expedient or safe. In every case we ought to proceed slowly and circumspectly, not forgetting that a small degree of force, continued for a long time, will in general be equivalent to a greater force hastily exerted, and with infinitely less detriment to the mother or child. But after some time, should we not perceive the head to descend, the force hitherto used must be gradually increased, till it be sufficient to overcome the obstacles to the delivery of the patient. It was before observed, as the head of the child descended, that the face would be accordingly turned towards the hollow of the sacrum, without any aim or assistance on our part. Of course the position of the handles of the forceps, and the direction in which we ought to act with them, should alter; for they becoming first more diagonal or oblique with respect to the pelvis, and then more and more lateral, every change in their position will require a differently directed action, because the handles should ever be antagonists to each other. In proportion also to the descent of the head the handles of the forceps should approach nearer to the pubes; so that, in the beginning of the operation, though we acted in the direction of the cavity of the pelvis, towards the conclusion we should act in that of the vagina. When we feel that we have the command of the head, by its being cleared of the pelvis, and the external parts begin to be distended, we ought to act yet more slowly, especially in the case of a first child, or there would be great danger of a laceration of the soft parts; and this can only be prevented by acting very deliberately in the direction of the vagina—by giving the parts time to distend—by duly supporting the perineum, which is the part chiefly in danger, with the palm of the hand—by soothing and moderating the hurry and efforts of the patient—and, in some cases, by absolutely resisting for a certain time the passage of the head through the external parts."

CLINICAL LECTURES,

Delivered at St. Thomas's Hospital,

BY SAMUEL SOLLY, Esq. F.R.S.

Assistant-Surgeon, and Lecturer on Clinical Surgery, at St. Thomas's School.

ON INJURIES OF THE HEAD.

GENTLEMEN,—The subject to which your attention was directed on the last occasion we met, shall be resumed on the present. You will, I have no doubt, remember my then warning you against considering any patient who has received a serious injury of the head as out of danger, merely because he shows no symptom of injury to the brain during the first few days. The value of such a warning has, I am sorry to say, been too truthfully illustrated in the sequence of the case I then detailed. I might well say that, in these cases, we know not what an hour may bring forth. For when we last met nothing could appear more favourable than the case related, though I have now to detail a fatal termination, from extensive cerebral lesion. I will first read to you my notes of the case to its termination, and we can then discuss the practical and physiological points of interest raised by its relation. After my lecture on the 24th, you will remember we found him apparently going on well, but as he still had pain in the head, I ordered twenty leeches, and Pil. Hydrar. gr. v. bis die.

25th.—No worse.

26th.—I received a message from the dresser saying that the man had passed a bad night, and was in a good deal of pain in his head, for which he had applied twenty leeches. I saw him at 1 P.M. His head has been relieved by the leeches, but he complains of pain at the external angle of the right orbit, which pain appears to him to rise upwards from the jaw, and to shoot over the head. He states that he is free from pain in the neighbourhood of the wound; his mouth is tender from the mercury. As the pain has so much of a neuralgic character, and possibly connected with this salivation, I ordered the mercury to be omitted, and the face to be fomented, after which an ointment containing acetic acid to be rubbed into the side of the face. At 5 P.M. when I saw him again, he had been relieved by the fomentation, but had not had the ointment, as there was not any acetic in the hospital. I ordered instead of it equal parts of the extract of belladonna and lard, to be made into an ointment and rubbed into the face.

Pulv. Jalap co. ℥j. hinc. nocte. M. S. C. cras. mane.

27th, 12 A.M.—Pulse 80, soft, and rather

weak; complains of his forehead and the side of the head, but no pain in the neighbourhood of the wound. His countenance was anxious and distressed; the right pupil was dilated; the left natural. I thought at first that this might possibly arise from the application of the belladonna, but he complained of having lost the feeling in his left hand, and that he could not lay hold of things so readily with it. I need hardly say I regarded this circumstance with the greatest concern, as I feared the worst from it. He had another very serious symptom, viz. that on lying down he complained of his head throbbing violently.

I ordered the twenty leeches to be repeated, and five grains of blue pill twice a day; the head to be raised in bed. Immediately I quitted the ward I called the attention of the pupils who were with me to the serious character of his symptoms, and gave an unfavourable prognosis.

At 8 P.M. I received a message from the dresser, informing me that he had had a fit, and when I arrived I found him just recovering from a third fit. The fits were not preceded by any scream, but in every other respect they were all of a true epileptic character. As soon as he began to recover his senses he went off again, and just previous to this he became very violent, and was with difficulty retained in bed. I inquired of his wife whether he had ever been subject to epilepsy: she said no, but that she had heard from his mother that when a child he had been subject to fits. Coupling the invasion of these fits with the incipient paralysis observed in the morning, I considered it not impossible that there was some irritation from the internal surface of the fractured bone. I therefore determined to trephine. This was accomplished by making first a crucial incision of the integuments, and then, by the application of the trephine on the lower edge of the fissure in the parietal bone. After the removal of the portion cut by the trephine, I removed with the dressing forceps a small portion of bone with a sharp edge, about the size of a thumb-nail, from under the superior edge of the fissure in the internal surface, which evidently pressed on the dura mater. About eight ounces of blood were lost at the operation, but very little afterwards. I performed it just after the commencement of the fourth fit, as I found he was too excited after he recovered from one to permit any operation willingly. He had one fit shortly after it was completed, but no more during the night. The dresser, Mr. Fixot, sat up with him, and he tells me that the patient complained of a good deal of pain in his head, referring it principally to the forehead and eyebrow, but sometimes to the back part, near the wound; he dozed at intervals, and then awoke with pain;

pulse very variable, sometimes thready, and sometimes a little fuller; cough occasionally occurred, always causing violent pain in the head.

28th, 9 A.M.—He has now paralysis of the whole of the left side of the head, body, and left extremity.

He knows me: complains of pain in his head, and wishes to sit up in bed: we raised him, and then he complained of being faint. I gave him a very little weak brandy and water, and ordered some sal volatile occasionally. His pulse is weak: 100.

28th, 10 P.M.—Has had nine fits at intervals during the day, the last about half an hour before I came down; he is quite sensible between the attacks; the sister thinks that he has lost some power in the right arm. As he was now dozing I would not disturb him; pulse 80, small, but not very feeble; skin hot. In one of the fits the convulsions were very slight, and confined to the left side of the body, and he seemed scarcely to lose his consciousness. I learned from the sister that she had observed twitching of the muscles on the left side during the afternoon of yesterday.

On Saturday he continued sensible, and he did not appear to lose his consciousness even during the fits, for as soon as the convulsions ceased he would take up his handkerchief and wipe his mouth. He had fits every half hour, which began at 9 in the morning and continued till 4 in the afternoon, when twelve leeches were applied to his head, and he had no more till 11 o'clock at night, when he had a very slight one, but at 12 he had a very severe one, which continued one hour; he was perfectly conscious, and breathing natural; scarcely ever complained of his head, and then referred the pain to the right brow.

Sunday, 30th.—He had no decided fits, only twitching of the muscles; remained sensible till about 4 o'clock in the afternoon, when a great change took place; he turned very pale, and had more twitching of the muscles, and at twenty minutes after four had a fit, which lasted an hour and a half. After this he totally lost the use of his inferior extremities; all consciousness left him, and he did not have another fit, but merely twitching of the muscles, and died at twenty minutes after 3, on the 1st of May, moaning a great deal and making a great noise, but for one hour before he died he never spoke.

Post-mortem, May 1st, 1 P.M.—Head. After the cranium was sawn through, about half an ounce of yellow pus escaped, while endeavouring to detach it from the dura mater. When this was done we found the internal table of the skull fractured more extensively than the outer table, split inward from the upper edge of the fracture. A

portion of this table which was thus split I had removed with the dressing forceps after using the trephine. The portion which remained could not have been removed without some force, as they were only partially separated from the surrounding bone.

At the time of the operation I did not detect this further depression, from a fear of separating the dura mater more than was absolutely necessary. But the appearance of this bone certainly teaches us that we are warranted in such cases (even in the absence of depression of the outer table, and the removal of the portions which are found at the edge of the opening made by the trephine), in searching carefully for any further portions that may have been separated.

Opposite this fracture there was a small opening in the dura mater of the size and shape of the extremity of the nail of the little finger, through which some softened brownish-coloured brain was exuding. On turning back the dura mater, we found on the same side the whole surface of the arachnoidea investiens covered with healthy yellow pus. The arachnoidea reflexa lining the dura mater was coated with a thick layer of pus, so tenacious that it almost amounted to a false membrane.

The brain, corresponding to the seat of fracture, was much discoloured. The centre of this discolouration was of a dark, dirty brownish hue, of a semi-liquid consistency, gradually becoming firmer, and shaded off to a dingy pinkish colour towards the circumference, which was spotted with deep bloody points: an horizontal section of the brain about half an inch from the surface showed this very distinctly. The disorganization extended downwards into the lateral ventricle at the commencement of the descending and posterior cornua, involving a portion of the transverse commissure, but not either the thalamus or corpus striatum. The surface of the brain, where the arachnoidea had been covered with pus, was slightly softened in many places, but most so over the inferior edge of the anterior lobes of the right hemisphere.

The hemispherical ganglion was scarcely, if at all, altered in its condition; its colour was healthy, neither paler nor deeper than usual; the edge, in some situations, was converted into a greyish-greenish tint, which Dr. Hodgkin attributed to a post-mortem action of sulphuretted hydrogen.

The pia mater and arachnoid on the left hemisphere were both perfectly healthy, and also on the surface of both hemispheres, where they are in contact with the falx major.

If the nature of the fracture in this case, and the injury inflicted on the brain and its membranes, as demonstrated by this post-mortem examination, could have been ascertained at the time of his admission, no one

could have hesitated to use the trephine. It is, then, a question for our consideration why this condition was not detected, and how far it would be desirable to adopt a different course when a similar case comes before us.

As a post-mortem examination does not demonstrate the amount of lesion of the brain at the time of his admission, for much that we now observe is the result of subsequent inflammation and gangrene, let us endeavour, reasoning from other cases and the physiology of the subject, to establish this point.

At the time of his admission it is very clear that the internal table of the skull was more extensively fractured than the outer, and that the fractured portions were partially depressed. Notwithstanding the entire absence of all symptoms of compression, these symptoms, as almost universally agreed to by surgeons, consist of an entire loss of consciousness; the mental faculties are smothered, and they cannot be roused. Many of the functions of vegetative life are also interfered with, the breathing is laborious and stertorous, not unfrequently the sphincters are relaxed, and the excretions are evacuated involuntarily. There are sometimes other symptoms, but these are the most common.

You will naturally say, if such are the symptoms of compression, why were they entirely absent in this case, where we see that the inner table was depressed and driven in upon the brain? I am inclined to believe that the acknowledged symptoms of compression depend upon the extent of the hemispherical ganglion which is pressed upon suddenly, and that if only a very small portion of this ganglion is pressed upon, then its functions are not naturally impaired, in this case, and many others that might be quoted: nevertheless, you must not consider it more than an hypothesis of my own, and not as an established principle. Nevertheless, I conceive this is the only truly physiological explanation of this apparent anomaly.

The splintered portion of the skull lacerated the dura mater to a very small extent, and to about the same extent, but no more, was the hemispherical ganglion originally injured. The medullary or fibrous substance beneath was so shaken that blood was effused in small points, as may sometimes be observed in cases of simple concussion without fracture. You will be surprised, on referring to treatises on injuries of the head, to find so many cases recorded in which very serious injuries to the brain have been unattended by serious symptoms of disturbed intellect, but, as far as I can judge from the loose mode in which post-mortem appearances are almost invariably detailed, they are all cases in which the injury is confined to the base of the brain, or the hemispherical ganglion has been but slightly injured in the first instance. It is a pity that

surgeons who have written on this subject should have neglected to state the exact extent of the surface injured, for this fact is equally important in its physiological as it is in its pathological bearing; the ignorance of it having induced some well-meaning but foolish people to quote such uses in proof of their theory that the brain is not the organ of the mind—not distinguishing between the ganglion which is connected with the mind, and those which are not. The following case, quoted by Mr. Guthrie from Dupuytren, illustrates my view of this subject.

A young man had received a wound in the head from a knife, which healed in the usual way, leaving only a little pain which occurred occasionally round the cicatrix. Some years after he was brought to the Hôtel Dieu in a state of stupefaction, with which he had been suddenly seized. An incision having been made through the cicatrix, the point of a knife was seen sticking in the bone, the removal of which gave no relief. The trephine was then applied without any result. The paralysis continuing on the opposite side to that on which the wound had been received, it was thought right to open the dura mater, and then to plunge the knife into the brain, when a large quantity of pus escaped. The paralysis ceased that night; he recovered his speech, became sensible, and entirely, though gradually, recovered.

In this case we may conclude, from the account, that the ganglion was only injured to the extent of the breadth and thickness of the knife, and no disturbance of the mind followed until an abscess formed, which, pressing on the ganglion from within, indicated its presence by the stupefaction and paralysis that followed.

The evacuation of the matter relieved the pressure, the senses returned, and the paralysis ceased.

Whether this explanation of the fact that you do meet with cases of depression of the table of the skull without the ordinary signs of compression of the brain, be true in its physiology or not, the fact itself is a most important one for you to remember, for its practical bearings. I shall again advert to it when I criticise my treatment of the case.

On referring back to its progress, you will remember that on the 8th, 9th, and 10th days after the accident, he was almost free from untoward symptoms: so well indeed had the case gone on, that my friend Mr. Travers, who had watched it with some interest, congratulated me on the favourable result of the anticipatory treatment which I had adopted. It may be fairly considered that these antiphlogistic measures which were practised so early stayed for the time the invasion of inflammatory action, though they did not entirely arrest it. His system was brought under the influence of mercury within 24 hours of the oc-

currence of the injury, and though he was not bled from the arm, for he never had a pulse exhibiting sufficient vascular action to justify it, 148 leeches were applied to the head.

The cough was much subdued by the ipecacuanha and conium pill, a blister, and the tincture of iodine to the chest.

But still the mischief went on, and thus I believe the fibrous medulla beneath the hemispherical ganglion became softened, as indicated on the eleventh day, by slight loss of sensation in the left hand. If the medulla had been materially altered in its texture, at the time of his admission, by the blow, there must have been paralysis at that time, and the fact of its not appearing till the eleventh day shews how slowly the softening and disorganization must have proceeded. The softening increased, and then an epileptic fit takes place, quickly succeeded by another, and another, and another, until, by means of openings made with the trephine, a splinter of bone was removed.

The principal cause of irritation is removed, and one more fit occurs immediately, and then they cease for about twelve hours, when they again recur, and though occasionally stopped for a short period by local blood-letting, they return at intervals, until the patient becomes quite insensible, remaining so for twelve hours previous to his death. This loss of consciousness I attribute to the pus we found effused on the surface of the brain, for until the pus was effused there was nothing to interfere with the hemispherical ganglion, and therefore nothing to affect the intellect; and neither the quantity or quality of the pus was such as might not have been effused in the course of twelve or fifteen hours at the longest. I think the inflammatory action which caused it was occasioned by the epileptic fits, and not the cause of them. The cause of the fits I believe is to be found in the softening and gangrene of the fibrous or conducting substance of the brain.

Taking this view of the progress of the case, we cannot avoid the conclusion that if this patient had been trephined when he was first admitted he would have had a better chance of recovery than by postponing it; and though it is impossible to say whether the brain was or was not so much injured at first as to have been irremediable, I candidly confess that I do not believe it was; for if such had been the case there must have been some symptoms of such a lesion, and it is astonishing from what serious lesion, both primary and secondary, the brain will recover. No, gentlemen, I believe that most all the disorganization which the post-mortem examination exhibited in the right hemisphere of the brain was the result of inflammatory action, excited by the irritation of the fractured skull, and partly kept

up and aggravated by the concussions occasioned by the cough. The number of cases on record in which patients have recovered whose brains have been seriously wounded, when the cause of irritation has been removed, should encourage you to make the attempt as early as possible to relieve your patient, if you can discover that any cause of irritation exists. The difficulty in the present case was to ascertain the fact of depression of the internal table.

There is no point in surgical practice regarding which there is and has been so much difference of opinion as the use of the trephine. Mr. Abernethy's Treatise on Injuries of the Head was called forth in consequence of the difference of opinion regarding the line of practice that ought to be followed in particular cases. He relates seven cases of fracture, with depression, which occurred within one twelvemonth at St. Bartholomew's, that recovered without any operation, "showing that a slight degree of pressure does not derange the functions of the brain, for a limited period at any rate, after its application." After relating other cases, he goes on to say—"Such cases ought to deter surgeons from elevating the bone in every instance of slight depression, since by the operation they must inflict a further injury upon their patients, the consequence of which it is impossible to estimate. From all, therefore, that I have learned from books, as well as from the observations I have made in practice and from reasoning upon the subject, I am disposed to join in opinion with those surgeons who are against trephining in slight depressions of the skull, or small extravasations of the dura mater."

Benjamin Bell, whose System of Surgery was published in 1801, says, "Hitherto it has been a general rule to consider the application of the trepan as necessary in every fissure, whether any symptoms of a compressed brain have occurred or not, but due attention to the real nature of the fissure, and to the effects most likely to result from perforating the skull, will show, that although fissures may be frequently combined with such symptoms as require the trepan, yet that they are not always, or necessarily so; and unless when such symptoms actually exist, that this operation, instead of affording relief, must frequently do harm; for it is by no means calculated for, or in any respect adequate to, the prevention of these symptoms, and I have already endeavoured to show that laying the brain bare is never to be considered as harmless, and therefore that it should never be advised but where it is probable that some advantage may be derived from it." In the present day these observations of Mr. Bell seem almost superfluous, *but when we find such precepts as the following inculcated by John Hunter in his*

Surgical Lectures, we need not be surprised that subsequent teachers of surgery should have felt the necessity of warning their pupils of the too free use of the trephine. "As we cannot tell for certain at the time," says Mr. Hunter, "whether the symptoms arise from concussion, compression, or from extravasation of blood, it may be more advisable to trepan, *as the operation can do no harm.*"

Mr. Lawrence relates an interesting case in a clinical lecture, published in the MEDICAL GAZETTE, vol. xxi. p. 345, of a boy who recovered without operation, in whom the skull was fractured and depressed, the brain wounded, and portions of it extravasated through a laceration of the scalp. "In this case Mr. Lawrence says, as the bone was here evidently and considerably depressed, and as it was also probably driven in upon the brain, it would, I believe, have accorded with the principles of treatment generally admitted, to have performed an operation for the purpose of elevating and removing depressed and detached portions of the bone."

"The considerations which determined me to do this were, the favourable state of the patient generally, and in particular the absence of all symptoms indicating compression of the brain; the specimens in pathological collections, of very extensive injuries of the skull repaired by a natural process; the smallness of the external wound, which brought this case nearly into the state of simple fracture; the extensive incision of the integuments, and exposure of the bone, dura mater, and brain, which an operation would have involved; and the almost invariable fatal termination of such proceedings within my own experience in hospital practice."

Dr. Hennen, in his admirable work on Military Surgery, relates many cases to show that the trephine should not be used, even when the bone is evidently depressed, in the absence of symptoms. He says, p. 288, "We have here sufficient proof that there is no absolute necessity for trepanning merely for depressed bones from gunshot, although few would be so hardy as not to remove all fragments that came easily and readily away." You will do well to read all the cases which he relates, and in the hope that most of you will do so I will only quote one short history in connection with the case before us. "A soldier was shot in the head in the Canadian campaign. A fracture was the consequence, with a depression of not less than an inch and a half; but as no untoward symptom occurred no operation was had recourse to. This man recovered, and went to the rear, where, at a distance of several weeks afterwards, he got an attack of phrenitis from excessive

drinking, and died. As the existence of the ball in the brain was strongly suspected, an inquiry was made after death, and on dissection it was found lodged in the corpus callosum."

Mr. Guthrie, in his interesting and valuable work on *Injuries of the Head*, lately published, makes some excellent remarks on the best mode of proceeding in these obscure cases. "The inner table, (says Mr. Guthrie) is sometimes broken in a peculiar manner, to which I believe attention has only been drawn by myself in my lectures, since trepanning has ceased to be the rule in all cases of fracture. In these cases the skull is cut rather than broken by a sharp cutting instrument such as an axe, sword," &c., just in fact as a piece of wood might be, while the inner table, like a piece of glass or brittle steel, is broken and splintered inwards. "These cases, says Mr. Guthrie, should be examined carefully. The length of the wound on the top, or side, or any part of the head which is curved and not flat, will readily show to what depth the sword or axe has penetrated. A blunt or flat, ended probe should in such cases be carefully passed into the wound, and being gently pressed against one of the cut edges of the bone, its thickness may be measured, and the presence or absence of the inner table may thus be ascertained. If it should be separated from the diploe, the continued but careful insertion of the probe will detect it deeper in the wound; a further careful investigation will show the extent in length of this separation, although not in width, and will, in all probability, satisfy the surgeon that those portions of bone which have thus been broken and driven in are sticking in or irritating the brain. In many such cases there has not been more than a momentary stunning felt by the patient; he says he is free from symptoms, that he is not much hurt, and is satisfied he shall be well in a few days."

"An officer was struck on the head in Halifax, Nova Scotia, by a drunken woman with a tomahawk or small Indian hatchet, which made a perpendicular cut into his left parietal bone and knocked him down. As he soon recovered from the blow, and suffered nothing but the ordinary symptoms of a common wound of the head with fracture, it was considered to be a favourable case, and was treated simply, although with sufficient precaution. He sat up and shaved himself until the fourteenth day, when he observed that the corner of his mouth on the opposite side to that on which he had been wounded was fixed, and the other drawn aside, and that he had not the free use of the right arm, so as to enable him to shave. He was bled largely, but the symptoms increased until he lost the use of the right side, became comatose, and died. On

examination the inner table was found broken, separated from the diploe, and driven into the brain, which was at that part soft, yellow, and in a state of suppuration." After relating several other instructive cases bearing on this point, he says, "the principle being laid down that it is right and proper to examine all such wounds with a blunt flat probe, in order to ascertain if possible whether the inner table is depressed or broken, the question necessarily arises, what is to be done when such depression and breaking down of the inner table is ascertained to have taken place? There can be no hesitation in answering that in all such cases the trephine should be applied, although no symptoms should exist, with the view of anticipating them."

"The old doctrine, it may be said, in regard to fractures generally, is revived in these cases, but on a principle with which our predecessors were not sufficiently acquainted. A patient very often survives a mere depression of the skull; he may, and occasionally does, survive a greater depression of the inner than the outer table; but I do not believe that he ever does survive and remain in tolerable health, after a depression with fracture of the inner table, when portions of it have been driven into the dura mater. If cases could be advanced of complete recovery after such injuries, I should not consider them as superseding the practice recommended, unless they were so numerous as to establish the fact that wounds of the dura mater and brain are not extremely dangerous. I have referred purposely to many cases in which a cure was effected after a lapse of time by the bone being removed; but they rather support than invalidate the principle I have inculcated. There are great objections, I admit, to the trephine being applied in ordinary cases of fracture, which are not attended by symptoms of further mischief; but the nature of the cases which I have particularly referred to having been ascertained, I maintain that the practice should be prompt and decisive in every instance in which the surgeon is satisfied that there is not merely a slight depression or separation of the inner table, but that several points of it are driven into the dura mater."

I have thought it incumbent on me to dwell very fully on the justifiableness of the use of the trephine in such fractures of the skull where there is an absence of cerebral symptoms, lest I should have practically misled you by attaching too much importance to this circumstance in my former lecture. Nevertheless, I cannot recommend the use of the trephine in any case, unless you have very decided evidence of a wounded dura mater from splintered portions of the inner table. "If there be any doubt," says the same authority, "on the mind of the

surgeon whether there are, or are not, any portions depressed and irritating the brain or its membranes, he should wait; and in this it is that the real difference between modern surgery and that of the olden time exists, with respect to adults.

The nature of the fracture in this case rendered it almost impossible to ascertain the fact of fracture of the inner table by means of the probe, as recommended by Mr. Guthrie.

You will perceive, gentlemen, from these few quotations, that there is still considerable difference of opinion as to any general rule for the use of the trephine in fracture of the skull. It must, indeed, be admitted that no general rule can be laid down, but that every surgeon must be guided by the peculiar circumstances of each particular case, bearing in mind that there are cases of injury of the brain in which the trephine may be required, though all the symptoms of *compression* are absent. Such cases, it is true, are rare, and their diagnosis difficult, but it is only by the remembrance of their occasional existence that you will ever detect them.

And, on the other hand, scarcely any extent of wound of the skull, the brain, and its membranes, accompanied with unequivocal depression of bone, should discourage you from the operation, if the functions of vegetative life are not so seriously interfered with as to make a fatal result inevitable; for the records of surgery teem with cases showing from what serious injury of the brain some patients will recover.

The following case, which some of you may remember, will come under this head, and also illustrate the usual symptoms of compression, and the first effect of such an operation.

James White, set. 49, was admitted into St. Thomas's Hospital at half-past 9, A.M. of the 13th of July, 1842. When I visited him at 12, I found him with an incised wound of the scalp, with a corresponding fissured fracture of the skull on the left side, extending from the occipital bone across the parietal bone and coronal suture into the frontal bone. The brain was oozing out at the posterior portion of the fissure, and it was reported that he had lost a large quantity of blood. The wound was inflicted with a large bill-hook as he lay asleep (by a man who intended robbing him.) When admitted he was quite sensible, and answered all questions rationally, but when I saw him about two hours subsequently it was difficult to rouse him, and his answers were not clear. The muscles of his face were paralysed both as regards sensation and motion, for he was *quite unconscious* of my touching him, even *when I pinched him sharply*. On examination of the wound I found a portion of

depressed bone driven under the edge of the upper portion of the parietal bone, and as it was evident that it could not be removed without a larger opening in the skull, I determined, with the advice of Mr. Green, to trephine the cranium, and remove it. The operation was performed without difficulty, and with scarcely any expression of pain on the part of the patient.

Three pieces were removed, two about the size of a square inch, one the size of a finger-nail, besides the portion removed by the trephine. A smaller, but very sharp, portion was driven through the dura mater and wounded the brain. The immediate effect of the removal of the bone was very striking. The patient at once complained of pain, and articulated quite distinctly, which he could not do before the operation. The sensibility of the skin of the thigh was also restored, as he felt my fingers when I touched him, though not so distinctly as in the perfect state. The arterial blood flowed very freely, but the bleeding did not last long after the removal of the bone.

Ordered him Hyd. Chlorid. gr. v. 4tā. quaque horā s., and cold water to the wound.

11 P.M.—Much the same as when I left him; has been dozing.

14th, 1 P.M.—Not quite so sensible as yesterday; skin hot; very thirsty; pulse 120; has taken six doses of calomel; mouth slightly affected; mercurial foetor; bowels open once pretty freely.

Cal. gr. j. 6tā horā s.; Hirud. x. capitis lateri sinistro et.

9 P.M.—Has been dozing all the afternoon; complains of his head when roused; cannot speak distinctly, but his answers are rational; skin very hot; pulse 140, sharp and small; very thirsty.

Ordered—V.S. ad 3xvj. Enema Communis.

Expressed himself, in answer to my inquiry, relieved by the bleeding.

15th.—Much the same; still sensible, and complains of pains in his head; mouth scarcely so tender.

Hirud. xxx. capit.

16th.—Scarcely any difference in his condition; says his head is not so painful; wound gaping; no fungus cerebri. Mr. Green advised my not pushing the mercury further, and to apply a poultice instead of the lint, considering it of great importance to establish suppuration.

Ordered—Cataplasma Panis. To omit the mercury.

19th, 10 A.M.—Much the same; pulse 120; skin very hot; complains of pain in the head.

Ordered Hired. xxx.

10 P.M.—Sinking; quite rational, but very low, can scarcely answer; pulse too quick to count; gave him two ounces of brandy; had very little effect upon his pulse. Ordered it to be renewed in the night if he lived.

20th.—9 A.M.—Sensible, but more depressed than last night; has taken some more stimulus during the night: sank gradually, and died about 11 o'clock.

Post-mortem.—Fracture extending from the centre of the frontal bone across the left parietal bone into the lambdoidal suture, which was separated slightly, so as to admit blood enough to make its course for about an inch in extent. The dura mater was divided for about four inches. The surface of the brain opposite the wound was softened, red, and pulpy. The disorganization extended downwards for about an inch and a half in its deepest part. Surrounding this softened portion for about half an inch, the brain was dotted with red points, and a little beyond it was in spots rather yellow. The surface of the brain on the left side was coated by a very thin yellow tawny layer of ill-formed pus. The right side normal; the corpora striata, thalami nervorum opticorum, and the rest of the brain, healthy.

This case is interesting in many points of view.

First, the intellect remaining so perfect, notwithstanding the extent of the brain that was injured. This circumstance confirms the theory stated elsewhere, that incised wounds of the hemispherical ganglion do not, in the first instance, affect the intellect so much as a compressing force; because the extent of surface which is injured is less in the former than the latter injury in the first instance; though as soon as blood is extravasated, and softening of the ganglion follows, then the senses are oppressed and subsequently obliterated.

Secondly, that the removal of the bone should have almost perfectly restored the functions of the nerves of sensation, which had been obliterated by its pressure, while it had no effect upon the motor tract.

Thirdly, the proof it affords that both motion and sensation may be interfered with, without the corpora striata and thalami nervorum opticorum being injured. In a practical point of view, I had some doubt as to whether I had pushed the depletion too far, as the man seemed exhausted; but the membranes exhibited quite sufficient indication of inflammatory action to justify the treatment most fully, and shewed how high it would have run if it had not been checked.

To return to Wingrove's case: the next practical point which the consideration of it suggests is, whether you are justified in open-

ing the dura mater when it has been exposed by the trephine, in those cases in which there are symptoms of pus beneath its surface.

The dura mater, when exposed by the removal of a portion of the skull, will be seen to rise and fall with the pulsations of the brain, if it is not separated from the dura mater by anything else than the other investing membranes. It is true that in a tranquil state, and with a small opening, the motion is very slight. The absence of this motion is stated by Mr. Guthrie as diagnostic of fluid beneath. "I have seen," says this author, "on the removal of a portion of bone, the dura mater rapidly rise up into the opening, so as to attain nearly the level of the surface of the skull, totally devoid however of that pulsatory motion which usually marks its healthy state; and an opening into it under these circumstances has allowed a quantity of purulent matter to escape, proving that the unnatural elevation of the dura mater was caused by the resiliency of the brain, when the opposing pressure of the cranium was removed. I consider this tense elevation, and the absence of pulsation, to be positive signs of there being a fluid beneath requiring an incision into the dura mater for its evacuation. It is a point scarcely, if at all, noticed in English surgery, although much insisted on in France. It was not in the slightest degree understood till the commencement of the war in the Peninsula, and was one of those points which particularly attracted my attention."

In Wingrove's case no such phenomena were exhibited at the time of the operation, nor did I perceive it when I examined the wound at my daily visits, which would rather confirm the opinion that the pus was not effused until about twelve or fifteen hours before death.

If I had observed this sign of the presence of matter under the dura mater, I confess that I should have punctured it, though I cannot believe, from the post-mortem examination, that the operation would have altered the result, as nothing could have changed the gangrenous condition of the brain. There are many other points of interest connected with injuries of the skull, and the use of the trephine, which do not bear upon the present case, but which I shall take the first opportunity of bringing before your notice.

I cannot conclude these remarks without expressing the hope that the study of this case will impress you with the importance of making a very careful diagnosis and prognosis in all injuries of the skull; and that while you value the trephine and elevator as most useful instruments for the relief of a compressed and irritated brain, that you will never be tempted by the prospect of per-

forming (what, if successful, is certainly a brilliant operation, but blamefully mischievous if the condition of the parts should not absolutely require it,) without having first a well-grounded conviction that their use can alone save the life of your patient; remembering that in all such injuries the great danger to be apprehended is inflammation of the brain and its membranes, and that nothing is so likely to produce it as their exposure to their air, and the forcible removal of their natural protectors.

REMARKS
ON
THE INJURIOUS EFFECTS OF
MESMERISM.

By GEORGE SOUTHAM,
Surgeon to the Salford and Pendleton Royal
Dispensary, Manchester.

(*For the Medical Gazette.*)

IN November 1841, Monsieur La Fontaine visited Manchester to exhibit the phenomena of animal magnetism; and having succeeded in producing its influence on a few individuals of known respectability, it soon acquired great popularity. It became the subject of conversation and experiment among almost all classes of society, and several persons were found more or less susceptible to its effects. Somnolency and catalepsy were produced in some; others were seized with various anomalous symptoms bearing the strongest affinity to those of hysteria; and, in a few instances, convulsions of a tetanic or epileptic character were excited. Such surprising effects soon made converts amongst the lovers of the wonderful and marvellous, but the profession generally received them with caution. Accordingly, with a few exceptions, the practice of the art continued in the hands of the charlatan, who, always ready to take advantage of the credulity of his fellow creatures, seeks every means which folly and imposition can invent to seek temporary fame and wealth. Besides the thumbing and staring, as practised by La Fontaine, other methods are stated to be capable of producing its phenomena; and, either from ignorance of the known physiological truths, or more probably from a desire to delude, new theories, so framed as to excite the curiosity of the ignorant, have been continually vaunted forth to explain effects which, in many

instances, are merely those of monotony and an excited imagination. With the cool effrontery peculiar to such people, they have pretended to restore sight to the blind, hearing to the deaf, and speech to the dumb. The bedridden and paralytic have been said to walk at their pleasure, and women to have had no longer occasion to fear the pains of labour.

It is unnecessary, in a medical journal, to prove the futility of such extravagant pretensions. If animal magnetism has any claim on our notice, it is not on account of any remedial power it possesses, but from the mischievous consequences it produces by exciting dangerous diseases of the nervous system.

Its advocates regard it as a peculiar agent existing within the living body under the direction of the will, which may be transmitted from one person to another, producing effects in the recipient which are not possessed by the individual communicating the impression. Doubtless such an agent is necessary to explain those anomalous symptoms presented by the O'Keys, and numerous other individuals, whose cases have operated so wonderfully on the credulity of its partisans; but to those whose minds are accustomed to more cautious reflection and observation, the proofs adduced in support of such a doctrine are too ambiguous and contradictory to enable them to admit the existence of such an agent. Besides, we are sufficiently familiar with the laws of the nervous system to explain many of the phenomena produced by mesmerism, provided we separate the real effects which it occasions from those merely the result of imposition and collusion.

The following case appears to illustrate its nature, and is a good example of the dangerous consequences arising from its application. A young man, aged 18, was mesmerised by one of his companions in December 1841, in the following manner. They pressed their thumbs together, and looked steadfastly at each other in the face, the operator at the same time gently moving his fingers over the palms of the patient's hand.

In about twenty minutes from the commencement of the experiment, his fingers, which had previously been half bent, gradually extended themselves; the arms became similarly affected; afterwards, the muscles at the back of the neck, and those over the whole

body. A feeling of coldness came over him, and a sense of tightness across his head, as if it had been bound firmly with a bandage. After remaining motionless and stiff a few minutes, he was seized with slight convulsive movements in the face; shortly the whole body was violently agitated, and he fell from the chair on which he had been sitting. These convulsions continued about 15 minutes, and in three quarters of an hour from the commencement he had perfectly recovered. He had allowed the experiment to be repeated several times before I saw the effects. This was a week after the first experiment. I mesmerized him in the manner described, and in less than five minutes the whole of his body was in a state of tetanic rigidity. This was quickly followed by contractions of the muscles on the right side of the face, afterwards of the whole body. The vessels of the head and neck became distended with blood, and the countenance bloated. The eye was turned upwards, or rolled about in the socket, the pupil sometimes dilated, and insensible to light; at other times it was contracted to a pin-point. The action of the heart was much increased, and the pulsations of the carotid distinctly seen. He frothed at the mouth, and his face at times was violently distorted. In about ten minutes the convulsions began to subside, and he fell into a deep sleep, from which he awoke in a quarter of an hour, suffering no other inconvenience than a slight but transient headache, and feeling of lassitude. During the paroxysm the power of feeling was destroyed, but consciousness remained. He states that at the onset he has sufficient control over the symptoms to cut short the paroxysm; but when the convulsions have set in, all power is lost, and he feels as if he had the will to rouse himself, but has not the power to do so—a sensation similar to that experienced on awaking suddenly from a profound sleep. Six weeks afterwards I witnessed a second attack in company with Mr. Jordan. Here it was produced by looking at an image, at the same time keeping the mind abstracted from all other subjects. In less than five minutes the patient fell backwards in my arms, and before I could place him on the floor his body was in a complete state of tetanic rigidity. *To this succeeded convul-*

sions and their attendant symptoms, which continued longer, and were more violent, than on the previous occasion. On recovering, he mentioned some conversation that passed between Mr. J. and myself, proving that consciousness remained; but, as on the former occasion, pinching and pricking gave him no pain. Some weeks afterwards I found that his system had become so susceptible from repeated impressions that he could excite a paroxysm in a few minutes by a mere effort of the will. With respect to his previous history, it may be stated that he is of an excitable and nervous temperament, but has always enjoyed good health. There appears to be an hereditary tendency to nervous affections in his family; for similar symptoms have been produced by mesmerism in his sister, who is about 14 years of age. His maternal grandfather is paralytic, his mother had an attack of the same disease in her 36th year, and two of her uncles died from apoplexy. The case presents several remarkable circumstances. It at once points out the dangerous consequences of mesmerism, and satisfactorily shews the means through which it exerts its influence. The symptoms certainly differ from those generally produced, and it may be stated that they are not the result of mesmerism. But the same objection would apply to those met with in the O'Keys, and in Mons. La Fontaine's two travelling patients. Further, those on whom it produces any influence are generally characterised by a similar condition of the nervous system, and the actions of the body in such persons being more under the control of the imagination than the will, they are very susceptible to external impressions, whose effects are in proportion to the individual's susceptibility. Precisely as the same feeling which excites pleasure in one produces a degree of ecstasy in another, and may be so exalted in a third as to occasion death, so likewise mesmerism may cause any of the various forms of nervous affections, from hysteria to catalepsy and epilepsy. The first application may require to be long continued before any effects follow; but when once excited they may be reproduced from the same impression more slightly applied; and thus by frequent repetition the system may be rendered so susceptible from a superinduced

habit as to act without any perceptible influence of the will.

Hence we may easily conceive how mesmerism exhibits its numerous phenomena, when we consider that it combines several means, all of which are powerful excitants of the nervous system. Externally the sense of touch and the sensibility of external parts are acted upon, by pressing the thumbs and gently moving the fingers over the palm of the hand; and vision is powerfully stimulated by the continual staring.

Internally it operates through the mind by mental emotion and the influence of attention, which enables us to transfer the sensorial power from one part of the body to another, giving rise to torpidity in the one, and an exalted condition in the other. The mesmeric power, therefore, is but a combination of exciting causes of disease, which are merely the "sparks that set fire to the train," their power of doing mischief depending on the degree of susceptibility of the constitution.

In the case described, besides an excitable temperament, there was an hereditary tendency to disease; two conditions extremely favourable for the production of a highly susceptible constitution. On stimulating the organs of vision and touch, with the co-operation of mental emotion, symptoms were excited closely allied to those of epilepsy; and from frequent repetitions the system became so extremely susceptible that a paroxysm might be produced by stimulating either of the senses; and ultimately the susceptibility had reached such a high degree, that, through the stimulus of the will alone, he could excite a paroxysm in a few minutes. A similar explanation may be given of the real effects produced in the O'Keys. One of these girls was subject to epilepsy, the other to hysteria, for the cure of which they were admitted into the University College Hospital. Dr. Elliotson states that one was said to have fits at such distant intervals that he could not tell whether she had any thing the matter with her. (See his *Elements of Physiology*.) By the aid of mesmerism he reproduced the disease, which has continued from time to time, with the addition of a variety of phenomena which can only be *classed with the mysteries of witchcraft*.

In the same way we may account for

the catalepsy and cataleptic ecstasy sometimes produced by mesmerism; and their comparative frequency amongst its phenomena may be regarded as a strong proof that the mind is chiefly concerned in their production, for when these diseases have occurred naturally they have generally been induced by inordinate excitement of the affections and passions, especially from contemplating some religious topics, in individuals with a highly excitable nervous system. The *Estatica* of Caldaro, and the *Adolorata* of Capriana, were probably instances of the real form of these diseases; by repeated attacks their systems have become so susceptible that they can produce a paroxysm voluntarily. The history of these remarkable deceivers proves that their diseases were excited by religious fanaticism. In addition to the cataleptic ecstasy they are said to possess marks of the stigmata and crown of thorns of Christ. The latter Lord Shrewsbury describes as being regularly and distinctly marked across the forehead by a number of small punctures, as if they had been pricked with a large pin, which was very probably the case: from the wounds he states that blood flows on certain occasions, generally on Saint days. Such effects being quite inexplicable by any of the known laws of nature, are attributed by their believers to the direct interference of God; consequently the girls have been named the Holy Virgins of the Tyrol. Religion is frequently used as a cloak for deception, and phenomena have been referred to Divine Agency by individuals who are as ignorant of the true principles of religion as they are of the laws of nature.

[To be continued.]

ON THE
NATURE, DIAGNOSIS, AND TREAT-
MENT OF INCIPIENT
PHTHISIS.

BY CHRISTOPHER M. DURRANT, M.D.
Physician to the East Suffolk and
Ipswich Hospital.

(For the *London Medical Gazette*.)

(Concluded from page 330.)

Recapitulation. — Having now examined in detail the various physical signs which obtain in the earliest stages of phthisis pulmonalis, it may be ad-

advantageous, prior to considering the treatment; briefly to recapitulate these phenomena, in the order in which they already stand.—We have, then—

1. Alterations in the form of the two sides of the chest, amounting, in some cases, to complete sinking in of the supra and infra clavicular spaces.

2. Insufficient expansion in the upper parts of the corresponding sides of the chest.

3. Decreased vocal and tussive fremitus, as felt below the clavicles.

4. Comparative diminution of the duration and intensity of the inspiratory murmur.

5. Augmentation of the intensity and duration of the expiratory sound.

6. Alterations in the character and quality of both murmurs, becoming rough, harsh, dry, &c.

7. The various rhonchi; the crackling or crumpling sound, dry at first, becoming afterwards moist; the plaintive, whining, or cooing note; and other occasional abnormal sounds, all indicative of the commencement of the disease.

8. Increased resonance, both of voice and cough, becoming more or less bronchophonic.

9. Undue transmission of the sounds of the heart through the tuberculated part of the lung.

10. Comparative dulness on percussion, with alterations in the quality of the sound elicited.

It will seldom occur, indeed it is scarcely possible, for all the above signs to exist at the same time in any one case of incipient consumption, although we are not unfrequently enabled to detect their successive appearance as the disease advances. The greater number that can be combined in any particular case, the more marked their character, and especially if, conjoined with general symptoms, the more accurate will our conclusion be, and the more decidedly may we pronounce on the positive existence of the disease.

Treatment.—Recent pathological investigations tend to prove that phthisis is not so invariably fatal as is generally supposed; “that it is not, like cancer, a disease of itself incurable, but that its extreme danger chiefly depends on the ordinary seat, extension, and relapses of the malady.” Such are the conclusions arrived at by M. Boudet, and recently communicated by him to

the Academy of Sciences at Paris. This author's investigations lead him to believe that recovery is possible at any period of pulmonary consumption; but that nature, independently of remedies, works the entire cure. That such will be the case in the occasional terminations of the advanced stages I am ready to admit; but that in the commencement of the deposit, very much towards a cure, or at least a suspension of the disease, may often be effected by treatment, I am fully prepared to affirm; and, as such, shall now consider the remedies which have, from time to time, proved decidedly beneficial, dwelling especially on those which my own experience has found of most value.

Blood-letting.—Among the various remedial measures had recourse to in the treatment of incipient phthisis pulmonalis, perhaps none has canvassed the opinions of the profession more than bleeding. Among its advocates are included many authors of the last as well as the present century, some of whom, acting under the impression of various preconceived theories, carried the practice to a very great extent. Like many other remedies, however, which have been proposed in this affection, the abuse, rather than the adoption of depletion, has, from the earliest period, given rise to the most conflicting opinions.

Viewing phthisis not as inflammatory in itself, but as peculiarly liable to excite that condition in the surrounding tissues, I am disposed to limit the use of general blood-letting (and then only in small quantity and seldom repeated), to such cases as clearly indicate signs of plethora, pulmonary congestion, inflammation, or hæmorrhage.

Laennec, speaking of bleeding in phthisis, says, “it ought never to be employed, except to remove inflammation, or active determination of blood, with which the disease may be complicated; beyond this, its operation can only tend to a useless loss of strength.” In a note by Dr. Forbes (to whom the profession is much indebted for first pointing out the importance of investigating the earliest changes in the respiration in phthisis, with a view to treatment), we read: “I have seen blood-letting much employed, and have myself used it much in this disease. I have seen great benefit derived from it, but chiefly in relieving the inflamma-

tory complications of phthisis. With our present knowledge of its pathology, it can hardly be expected to benefit the tuberculous affection, and my experience leads me to condemn its use in every case of pure phthisis."

Having, however, subdued pulmonary congestion, &c. by small general blood-lettings, the adoption of local depletion, by leeches or cupping, ought then to be substituted, especially in those cases in which co-existing bronchitis, hæmoptysis, or pneumonic consolidation, resulting from tuberculous deposit, still remain. At this period I strongly advise the application of six or eight leeches below one or both clavicles, or the withdrawal of four or five ounces of blood from between the scapulæ, by cupping. The former method is preferable, and should be repeated according to the exigency of the case, once a week or fortnight. This practice, by unloading the apices of the lungs, I have found to afford marked and permanent relief in the majority of cases, more especially by removing the sensation of tightness, pain, and general uneasiness, often so distressingly felt at the upper part of the chest.

It is in those cases of incipient phthisis accompanied by hæmoptysis, or complicated with bronchitis, that small, general, or repeated local depletions, so frequently prove of such decided benefit; in the purely chronic form even topical bleeding is less called for, save to remove accidental complications.

Counter-irritation.—Many have been the forms proposed, and great has been the testimony in favour of the adoption of this important remedy; important both as a palliative and also as a frequent preventive against the farther extension of the tuberculous deposit.

The use of counter-irritation in the treatment of phthisis appears to claim considerable antiquity. Both Celsus and Galen, whose attention however was only directed to the advanced stages of the malady, recommended the free application of revulsive plasters, and even the actual cautery, to the chests of their patients in this disease.

From a tolerably extended observation and experience of the comparative amount of benefit derived from the use of different counter-irritants, I am disposed to place the greatest reliance on the timely application of blisters, and

the use of a liniment of turpentine and acetic acid. If, however, much febrile excitement attend the disease, it will be advisable, in all cases, to postpone the application of blisters until after its removal by appropriate, general, or local depletory measures; otherwise they not unfrequently increase the evil they are intended to remove.

Small blisters, about an inch and a half in width, placed below the entire length of the clavicles, operate very favourably. Should, however, dyspnoea prove urgent, a large blister over the sternum seldom fails in affording marked relief. With a view to excite and keep up a moderate degree of counter-irritation, and, at the same time, to render the skin less easily affected by atmospheric changes and external impressions, I have hitherto found no application so useful and so manageable as a liniment of turpentine and acetic acid, first proposed by Dr. Stokes, and since advocated by Dr. Hughes. The latter author adopts a formula, which, for extemporaneous prescription, amply fulfils the intention: viz. one ounce of strong acetic acid and two ounces of the oil of turpentine, simply shaken together. I have, however, in a few cases of delicate skins, found it necessary to reduce the proportion of the acid.

The original formula employed by Dr. Stokes is the following:—

R. Olei Terebinth. ℥ij. ; Acidi Acet. ℥ss. ; Vitelli ovi. j. ; Aq. Rosar. ℥ijss. ; Olei Limon. ʒj. M. fiat Linimentum.

After applying this remedy freely to the chest night and morning for a few days, patients have often expressed themselves in almost enthusiastic terms of the relief afforded. The various lotions containing vinegar, alcohol, ammonia, mustard, &c., from time to time recommended, are all much inferior to the above. Tartar emetic, either in the form of ointment or solution, proves a useful, though, in chronic cases, by no means so decidedly effectual a remedy as the turpentine and acetic acid liniment. Croton oil has been held in considerable repute, and certainly fulfils the intention, especially as an application to the larynx and trachea.

Issues, setons, moxa, and even the actual cautery, have severally found their advocates; of the latter, from their painful application, and the great irritation which they inevitably pro-

duce, no further mention is necessary. The insertion of setons or issues is to a certain extent open to similar objections; nevertheless, an issue introduced alternately in each arm, and allowed to heal, will be a prudent course, especially at the age of puberty, in all cases whenever from hereditary or acquired predisposition an attack of phthisis is apprehended.

Emetics.—Since the publication of Sir James Clark's valuable work on Consumption, the practice of treating incipient phthisis by frequently repeated emetics has lately been revived, with a prospect, if persevered in, of beneficial results. The testimony of the numerous authors of the last century in favour of this measure, valuable as is their authority, must not be received without due limitation. The uncertain knowledge that then existed in detecting incipient phthisis, and the imperfect manner in which the pathology of mucous membrane and its secretions was at that time understood, renders it exceedingly probable that the majority of cases reported as relieved, or even cured, were not phthisis, but chronic bronchitis. One fact, however, is unquestionably proved, viz. that emetics may be administered for months, not only without injury, but with positive advantage; the appetite improving, the complexion becoming clear, and the patient gaining both flesh and strength under their continued use.

I have now had an opportunity of watching and treating very many well-marked cases of incipient phthisis, and the large amount of benefit which, in the great majority of instances, I have seen derived from a persevering use of emetics, makes me the more anxious to add the feeble weight of my own testimony and experience to that of others, in favour of the adoption of this remedy, both as a palliative and curative measure, in the treatment of the commencement of this too frequent disease.

The visible effects of the emetic treatment are, in general, the great alleviation, and frequently the entire removal, of the cough and dyspnoea, together with the pain and oppressive uneasiness in the chest, so frequently complained of in this affection. The changes in the expectoration under the use of emetics are very various; in some it is increased, in others di-

minished, or altogether checked. The complexion clears, and the appetite, if previously defective, I have generally found to improve; at the same time the secretions flowing more freely, and the bowels acting with greater regularity. The physical signs of the disease also frequently undergo a corresponding and equally favourable change; the expiratory sound becoming less loud and of shorter duration; the rhonchi cease; and nothing frequently remains but a slight roughness, audible only on a deep inspiration. The emetic which I have found to answer best, causing vomiting to occur twice or thrice, has been twelve to fifteen grains of powdered ipecacuanha, taken in warm water an hour before breakfast, and repeated daily, or less frequently, according to the peculiar exigencies of the case. A wine-glassful of cold camomile infusion, taken immediately the vomiting has ceased, imparts tone to the stomach, and prevents the distressing nausea which sometimes succeeds its operation.

The *modus operandi* of this remedy is, I imagine, two-fold—partly local, by dislodging the recently deposited tuberculous matter, and at the same time preventing its increase, and partly general, by giving a shock to the whole system, thereby improving the secretions, and restoring the due balance in the circulation.

In the selection of proper cases for the exhibition of emetics, some care and circumspection are necessary. If the tuberculous matter be deposited to a considerable extent, very little advantage can be expected from the use of emetics; indeed, the propriety of adopting them at this period becomes very questionable. The incipient stage alone is the period in which we clearly derive benefit from this practice; and, as a general rule, the more chronic the character of the malady, the more decidedly and sanguinely may we employ the remedy.

In those instances in which bronchitis or hæmoptysis co-exist, these should first be removed by appropriate treatment, and then the emetic plan may be safely adopted.

The existence of gastric irritation, as evinced by a dry, red, shining tongue, with prominent papillæ, thirst, a congested and swollen state of the fauces, and upper part of the pharynx, with or

without epigastric tenderness, strongly contra-indicates the use of emetics.

The only objection of which I am aware, that has been advanced against this practice, is the opposition with which the remedy would be met by the patients themselves. Hitherto, I confess, I have found very little difficulty in ensuring its regular adoption, and am disposed to attribute the non-compliance of the patient more to the want of decision and firmness on the part of the physician in enforcing the measure, than to the disagreeable nature of the remedy prescribed. One great recommendation of this practice is, that it need not, and indeed ought not, to interfere with any other treatment, which, according to the existing symptoms, may be considered most suitable to the peculiar condition of the case.

Iodine.—From the palpable effects which this substance exerts in the removal of enlarged glands, and scrofulous deposits in various parts of the body, which latter, in their intimate nature, do not apparently differ from the tuberculous, and from the very favourable testimony of several authors, founded on extensive trials of the remedy, the use of iodine and its preparations, in the treatment of incipient phthisis, unquestionably lays claim to the fairest considerations. The operation of this medicine is very slow, but acting, as it does, on the hepatic, renal, and uterine functions, the general health of the majority of patients rarely fails to improve under its use; and if the morbid deposit in the lungs be limited, the probability in many cases, of its absorption, is by no means chimerical.

The iodide of potassium, in doses of two or three grains three times a day, with a few grains of the sesquicarbonate of soda in any light infusion, is the form in which I have found the remedy to agree best. In leucophlegmatic habits, and where a more tonic effect is required, the iodide of iron may be advantageously substituted.

Sedatives.—The employment of sedatives, however valuable as a palliative measure in the more advanced stages of the malady, I have seldom found to be of much service in the very commencement of the disease, save in diminishing the irritation of the cough, and occasionally in procuring rest. The *hydrocyanic acid* does not appear to have

sustained the reputation in the treatment of phthisis which its advocates at first raised in its favour: nevertheless, in combination with morphia or conium, it is sometimes exceedingly useful in quieting the paroxysmal cough, which often, even at the commencement of the disease, proves so harassing and wearing to the sufferer. Hyoscyamus, in the form of tincture, is a valuable addition to the mixture of iodide of potassium and soda, above alluded to.

Digitalis may be advantageously prescribed in those cases of phthisis co-existing with cardiac affection, and especially if the habit be phlegmatic. The effects, however, of this remedy must be carefully watched, since by deranging the gastric and alvine functions, and permanently reducing the force of the circulation, the constitution will be thereby injured, and the disposition to deposit tuberculous matter in consequence increased. Perhaps, on the whole, the salts of morphia, commencing with very small doses, may be esteemed the most useful. In the inflammatory complications of the complaint, the tartrate of antimony, in combination with a sedative, will operate beneficially; but, from its liability to disorder the stomach and bowels, its use should be discontinued immediately the inflammatory symptoms have been subdued.

Mercury.—The exhibition of mercury in phthisis, save as an alterative, or in combination as a mild aperient, has been considered by the greater number of authors as decidedly injurious. More recently, however, the attention of the profession has been ably directed to the subject by Sir Henry Marsh, Dr. Graves, and Dr. William Stokes, of Dublin; and still more lately, in an interesting paper on the treatment of incipient phthisis by mercury, by Dr. Munk, published in the *MEDICAL GAZETTE* for Oct. 1840.

From the high talent and undoubted testimony of the authors above mentioned, and from the numerous well-marked cases which they have detailed, little question can exist but that in some cases of incipient consumption the production of ptyalism is attended with the happiest result; in reference to the adoption of this treatment, however, the precaution of Dr. Stokes should never be lost sight of: viz. "that the remedy is a two-edged sword, and

its exhibition must not be lightly attempted."

The form of the disease best adapted for the mercurial treatment is that in which the symptoms present more or less of an inflammatory character. In these cases, by the judicious use of mercury, the irritation of the pulmonary mucous membrane and parenchyma may be removed, the deposition of tuberculous matter probably arrested; and thus, by the suspension of local action, time is gained for the adoption of other remedies, and the improvement of the general health.

In my own practice I have tried the mercurial treatment of incipient phthisis in a very limited number of cases; where I have done so, however, the result has been more or less favourable.

Inhalation.—Of the utility of inhalation as a remedy in the early stage of consumption, I have at present had very little experience. Like the majority of curative measures, it has its advocates and its opponents; and on weighing the testimony of each, it is extremely probable that by judicious management, where there exists but little disposition to inflammatory action, it will prove a useful adjunct to the therapeutics of pulmonary disorders.

Sir Charles Scudamore strongly recommends a mixture of iodine with conium, inhaled from a glass apparatus with large tubes, by which treatment, combined with general measures, he reports that he has effected several cures. Dr. Corrigan prefers impregnating the air of the patient's room with iodine. Perhaps the most ingenious and economical method of introducing this substance into the system by inhalation, is that proposed by Dr. Leigh, of Jersey, who directs the patient to apply a sufficient quantity of iodine ointment on the ribs, under both axillæ, and then, by covering the head with the bed-clothes, to inhale the iodine that is volatilized by the heat of the patient's body. This practice may be advantageously adopted in hospitals, and as the ointment produces counter-irritation, I would suggest its simultaneous application below the clavicles.

Tonics.—After the removal of local, especially gastric irritation, and the more prominent symptoms caused by the presence of tubercles, the free exhibition of tonic remedies (with a view to improve the general health, by

altering the condition of the fluids and solids of the body, upon the depraved state of which the secretion of tuberculous matter undoubtedly in a great measure depends) may be most advantageously had recourse to: of these, iodine, the preparations of iron and zinc, the sulphate of quinine, and the mineral acids, are to be preferred. The sulphates of iron and quinine, with an excess of acid, I have repeatedly found, in conjunction with the exhibition of emetics, to act most favourably in this disease; indeed, the salts of iron, by improving the condition of the blood, have, and still most deservedly enjoy, a high reputation in the treatment of the early stages of pulmonary consumption.

Among the best tonics in incipient phthisis may be included—early hours, both in reference to rising and going to bed; at the same time, carefully avoiding excitement of any kind that may at all interfere with a quiet and unbroken slumber; a diet at once nutritious, unstimulating, and easy of digestion. Thus, for breakfast, I would recommend a lightly-boiled egg, with dry buttered toast, or bread a day old, and tea or cocoa, with a large proportion of milk; coffee, with an equal quantity of milk, may be taken if it agree, but in general I have found it too stimulating. For dinner (which should be an early hour, viz. 1 or 2), meat, principally mutton, beef, and game: veal, pork, and salted meats, are objectionable: fried fish and salmon must be rejected from the dietary of the phthisical patient; boiled sole, whiting, and haddock, however, are nutritious and digestible, and may therefore be allowed; a moderate proportion of well-dressed vegetables may be taken with the meat, with a small quantity of mild home-brewed beer; this is far preferable to porter or wine, which are too stimulating. The tea and supper should be combined, and consist principally of milk, or thin arrow-root, with toast or bread and butter; the last meal ought to be taken at least one hour before bed-time. In addition to the above, I would strongly recommend a tumbler of asses' milk to be taken twice a day, viz. on rising in the morning, and again immediately before retiring to rest.

Another admirable tonic is a residence where the air is mild and dry, to

the invigorating influence of which the patient should expose himself as much as possible, carefully avoiding easterly and northerly winds. He should live much in the open air, taking gentle exercise, the best of which by far, when attainable, is that derived from horse exercise. Sailing on the sea, when moderately agitated, if it do not excite too great nausea, is another valuable remedy in the early stage of the complaint; and, at this period, seldom fails in affording marked relief; cruising round the coast, at repeated short intervals, by avoiding the inevitable *ennui* consequent on a protracted sea expedition, is preferable. Travelling (provided the circumstances of the patient admit of the comforts of home, combined with the strictest regard to the improvement of the general health), by varying the air and scene, and at the same time tranquillizing the mind, proves, in many cases, a valuable auxiliary to the tonic treatment.

The shower-bath, if possible, should never be neglected by those in whom there exists the slightest predisposition to the tuberculous habit. It is astonishing the amount of benefit derived from this remedy as a tonic; it enables the invalid to bear with impunity the vicissitudes of climate, braces the system, gives tone to the digestive organs, and, by diminishing the susceptibility to the impressions of cold, prevents, in many cases, the first assumption of the disease. It should be taken every morning throughout the year on rising, and its use followed by brisk friction with the coarsest towels. If, in delicate individuals, the shock of the bath cannot be borne, or reaction does not immediately follow, rapid sponging of the entire surface of the body, succeeded by friction, must be substituted. In commencing either practice, it will be advisable to use the water slightly warm; the temperature, however, must be daily reduced, until it becomes cold, at which point it must be steadily kept and persevered in. Flannel ought always to be worn next the skin; and, during the winter months, I would strongly advise a chamois leather waistcoat being worn over thin flannel during the day, by all those who, from whatever cause, are more or less prone to the disease.

Having brought to a conclusion the consideration of those remedies which

have proved, both in my own practice as well as in that of others, of unquestionable benefit in the treatment of the early stage of pulmonary phthisis, it now only remains for me, in a few words, to notice the especial treatment of those forms in which the disease commonly obtains at its commencement, more particularly in reference to its complication with inflammation and hæmorrhage.

When bronchitis or pneumonia co-exist with tuberculous deposit, the proper remedies will be depletion, saline aperients, antimony, low diet, and the cautious exhibition of mercury to the extent of *slightly* affecting the system. Having, by one or more of these measures, subdued the inflammatory condition, the period then arrives for emetics, counter-irritation, and mild tonics; at the same time, by way of precaution, frequently repeating the topical bleeding by leeches below the clavicles.

When hæmoptysis is a prominent symptom in the early stage of phthisis, small and repeated general blood-lettings are advisable; saline aperients; nauseating doses of antimony or ipecacuanha; the mineral acids, with opium; the acetate of lead, with opium and acetic acid; or creosote, with opium; or lastly, in the event of all these remedies failing to arrest the bleeding, we may try what is now believed to be the active ingredient of Ruspini's styptic, viz. gallic acid, in doses of half a grain, three or four times a day.

Having, by the above practice, succeeded in stopping the bleeding, we may then, with advantage, commence the exhibition of emetics; the application of blisters to the chest; the use of tonics, especially iron and the mineral acids; with the other general measures already fully detailed.

If the disease be uncomplicated either by hæmoptysis or inflammation, which in the majority of instances is the case, we should at once commence the practice of emetics, counter-irritation, and iodine, with strict attention to the rules for diet and regimen above prescribed.

To ensure the beneficial effects of the foregoing treatment, it must be commenced *early, boldly, and continued perseveringly*; and although, in so fatal an affection as phthisis pulmonalis, and one the tendency of which

to a progressive and fatal termination is so great, many cases will inevitably occur in which apparently little benefit is derived from any mode of treatment; yet, on the other hand, I do conscientiously affirm, that by the timely and judicious exhibition of remedies, the disease, if not cured, may often be indefinitely suspended; and the lives of hundreds, in whom it now too frequently runs unchecked to its close, may be long preserved in a state of happiness and comfort.

**CASE OF ARTIFICIAL ANUS,
SUCCESSFULLY TREATED BY INCISION OF
ITS DIVIDED EDGES.**

To the Editor of the Medical Gazette.

SIR,

IF the following should be thought worthy of the pages of the *MEDICAL GAZETTE*, an early insertion will much oblige the writer.—I am, sir,

Your obedient servant,
D. MALCOLM, M.C.

Boston, May 20th, 1843.

John Barclay, æt. 47, farm labourer, for the last two years has been troubled with periodical prolapses of a reducible inguinal hernia, attaining sometimes the size of a hen's egg, and occupying an elevated position in the left groin. Previous to the last two months it has occasioned him but inconsiderable pain, and very little inconvenience, save that of assuming the horizontal position and reducing the tumor with his own hand. Never wore a truss, and says the rupture has frequently continued down for spaces of thirty-six and forty-eight hours without the occurrence of any unpleasant symptoms. About eight weeks ago, however, after a hard day's work, an unusual pain began to be felt in the seat of the tumor, which had now become exquisitely painful to the touch and defied all his attempts at reduction. The pain increased rapidly with the continuance of the rupture, and in seven hours afterwards all the symptoms of strangulation had supervened. A surgeon had been immediately called in, who, failing in all his attempts to effect reduction, and perceiving the alarming advance made by the symptoms, intimated to the patient the danger of his condition, and held out an operation as the only available means

of affording him relief. An operation accordingly was consented to, and in a few hours afterwards was carried into execution. The consequences were, that the bowel was reduced, and the urgency of the symptoms abated; but in lieu of the danger of the former tumor, there succeeded the loathsomeness and inconveniences of an artificial anus. Up to the present time the patient had been discharging his feces partly by the rectum, but in greater quantity from the opening in the groin; and had thereby, by the acrimony of the discharge, incurred extensive excoriation round about and in the neighbourhood of the latter situation. The wound occupied the middle third of the sulcus which divides the thigh from the abdomen, was two inches long, irregular in its edges, but capable of complete closure by the semi-bent position of the thigh upon the belly. Patient felt exhausted, and complained of great pain and tenderness in the back and sacrum, occasioned by the continued pressure of the mattress on which he lay on these parts. On dilating the edges of the wound, which were much inverted, and covered with spongy-looking skin, a quantity of wind and liquid feces made their escape, and obscured the internal orifice for a time, but which, by sponging and drying, was afterwards determined to be of the size of a shilling. As the patient was much reduced in strength, and on the point of being threatened with bed sores; and, moreover, as there were no marks of incarnation in the bottom of the wound, and no external evidence of a disposition to heal, it was proposed to the patient, as a means of increasing his present comfort and adding greater certainty to his recovery, to submit himself to the chances of a second operation. The proposal was readily acceded to; and on the following day, with an instrument prepared for the purpose, I proceeded to incise the edges of the wound, and afterwards to keep them in close contact, with the object in view of producing adhesion of their surfaces, and effecting a favourable termination to the disease. The instruments I employed for the purpose were a piece of iron wire bent into a parallelogram of the length and depth of the wound, and a common scalpel. By inserting the former perpendicularly

into the wound, and pressing first on one side and next upon the other, so as to make the respective walls of the wound to protrude through the opening, the necessary slice to be removed was thus conveniently brought within reach of the scalpel, and the operation was done without pain or loss of blood. The results fully realized my expectations: union took place by the first intention; and the man, grateful for his recovery, was able to resume his usual occupations in thirteen days.

EXTRACTION OF A NEEDLE FROM THE LEG,

SUPPOSED TO HAVE BEEN PREVIOUSLY SWALLOWED.

To the Editor of the Medical Gazette.

SIR,

MANY cases are on record, and some in the early numbers of your journal, of needles which, after being swallowed, have subsequently escaped from the surface of the body. Such results are usually described as attended with more or less unfavourable symptoms, local or general irritation, abscess, &c. I forward you a case, thinking it may be worthy of remark, in which a needle passed from the leg of a female, without giving rise to any thing but the most trifling degree of irritation.

A young woman, æt. 24, consulted me about eight weeks back respecting a small swelling about the size of a walnut, situated on the outer side of the calf of the leg. It was hard and very moveable, did not implicate the adjacent skin, and gave no pain unless roughly handled. When pressed with some force it gave a distinct sensation of crackling, and altogether disappeared, at the same time causing the patient to complain of a "pricking pain," which lasted until the tumor re-formed, which took place in a few hours. This was repeated several times. The inconvenience caused by the swelling was so slight, that no active remedies were called for. A light bandage and cold lotions afforded all the relief required.

At the expiration of eight weeks the swelling was not changed; but I was summoned to see her, and found the point of a needle projecting a line or two through the skin, directly in the

centre of the tumor. I easily extracted about two-thirds of an ordinary-sized sewing-needle, which had its surface completely oxidized, and the edges, where it had been broken, rounded and perfectly smooth. No pain, redness of the surface, or even the most trifling bleeding, followed its removal. A small quantity of thin colourless serum only escaped. The tumor almost immediately disappeared. The patient could not remember having swallowed such a body; but there can be little doubt of it, as I know her to be above deceit, and the fact of the point being the first to escape disproves any other notion.

I infer that this needle was surrounded by cysts: the crackling and subsequent temporary disappearance of the tumor upon pressure would justify such a conclusion.

This case may be of service to any who are consulted by persons rendered anxious on account of having swallowed a similar body.—I am, sir,

Your obedient servant,

C.

London, May 11, 1843.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

THE REVENUE IN JEOPARDY FROM SPURIOUS CHEMISTRY.

It was well said by Boerhaave that chemistry, though an excellent handmaid to medicine, was a bad mistress; and we may add that all the ordinary affairs of life admit with advantage her occasional interference, though they would be damaged by her constant direction.

Several instances have lately occurred where the revenue has been protected by skilful analysis from frauds which might have appeared at first too difficult even for modern chemistry to detect. Dr. Ure, whose analytic dexterity has conferred this benefit upon

the country, has given the history of his success in a pamphlet, of which we have placed the title at the head of this article.

It appears that in September 1842, a cargo of eighteen casks was entered at the Custom-house of Liverpool by Messrs. Tennants, Clow, and Co., under the title of *naphtha*, at a valuation in the whole of £50. It was suspected that the cargo was not really naphtha, and after the matter had been referred to the Board of Customs in London, a sample bottle was forwarded for analysis to Dr. Ure. In his report he stated that the liquor was not naphtha, but pyroligneous acid mixed with alcohol; or rather, as it should seem, spirits masked by a slight admixture of pyroligneous acid. One hundred parts of the fluid in the bottle contained ninety-one of proof spirits. "*The sprits thus distilled may be rendered quite palatable by rectification with potash, so as to be fit for making English gin.*"

In consequence of this report, the Commissioners ordered the goods to be detained for having been entered under a false denomination. The importing merchants now procured a contrary certificate from the Apothecaries' Hall at Liverpool, as well as one from Professor Graham, of the London University College. The Professor stated that the liquor was not convertible into gin by potash or by any other process; that it was not alcohol; that the small proportion of alcohol, if any, which it contained, was not separable from it; and that it contained no pyroligneous acid.

A memorial embodying these points having been presented to the Board of Trade, the matter was referred to the Board of Customs for re-consideration. Mr. Ross, the surveyor-general, was accordingly instructed to invite Dr. Ure to a consultation in his office. This took place on the 5th of January, when the certificates of Professor Graham,

and of Mr. Waldie, practical chemist to the Liverpool Apothecaries' Company, were laid before Dr. Ure. Mr. Graham's certificate, which appears to be the one already quoted, affirms that a small quantity of spirit in naphtha is exceedingly difficult of detection, owing to the impossibility of separating them when once mixed. He is unable, therefore, to say whether the naphtha contains a small quantity of alcohol or not; but he affirms that the alcohol could not be separated, nor used in making English gin by distillation from potash, or any other process whatever.

David Waldie, again, certifies that the naphtha gave no evidence of the presence of alcoholic spirit; but that it was merely pyroxylic spirit, or wood-naphtha, with less impurities than usual, on which account its flavour was more agreeable than ordinary: nor could it, in his opinion, be made a drinkable liquid by any chemical process.

Dr. Ure, having reserved the greater portion of the original sample bottle, performed a series of fresh experiments with it, and furnished the Surveyor-General's office with the result on the 7th of January.

He allows that alcohol and naphtha, being equally volatile, cannot be completely separated by distillation, or by any direct method: yet the thing can be done indirectly. In the present instance, however, it was easy to ascertain the presence of a large proportion of alcohol, without effecting this separation. The method was as follows:—When alcohol, fifty or sixty per cent. above proof, is mixed with its own weight of sulphuric acid, and distilled, it affords sulphuric ether; but when wood-spirit, or wood-naphtha, is treated in the same way, it affords, not a liquid, but an acriform product. Moreover, in the former case, if the distillation is continued too long, the residuum in the retort becomes

black, thick, and froths up with such impetuosity as to be projected out of the vessel, though fifty times as large as the liquid required before its intumescence; in the latter, the mixture neither thickens nor froths up. Now, after rectifying the imaginary naphtha by repeated distillations, Dr. Ure treated it with sulphuric acid, when it yielded a fine, fragrant, *liquid* sulphuric ether, and almost as much as the same quantity of alcohol would have done. A very little ligneous or methylic ethereal gas also appeared. In due time the residuum became black, frothed up, and was projected out of the vessel with great violence. "Thus by the product of fine liquid ether, and the intumescence in the retort, two infallible proofs of abundance of alcohol in the said naphtha are obtained—proofs which will be recognised in every chemical court in Christendom." Dr. Ure found, too, that four fluid ounces of the pyroligneous acid residuum saturated as much carbonate of potash as two fluid ounces of ordinary vinegar.

He naturally thought that the matter was now settled; but on the 18th of February he was again summoned to the Custom-House to consider two certificates signed by Mr. Brande, both denying the presence of alcohol in the supposed naphtha. Some little doubt, however, overshadows the denial, and Mr. Brande suggests the propriety of submitting the question to some third chemical authority.

Dr. Ure now requested to have a sample from each of the casks at Liverpool, and he accordingly received 18 bottles full of the naphtha, with the corks sealed with the Custom-House arms. The liquor was like the former sample. It had a sour empyreumatic smell, an acidulous taste, reddened litmus, effervesced with carbonate of soda, and had a specific gravity of 0.942.

Dr. Ure and Mr. Scanlan were occu-

pled for three weeks in experiments with this liquid, which fully confirmed the former ones, and showed that the "naphtha" was merely alcohol disguised with a little pyroligneous acid.

In the first place, Dr. Ure and his friend took half a gallon of the liquid from five of the bottles indiscriminately, and having distilled by the heat of a water-bath, obtained a spirit of sp. gr. 0.901, while an acidulous residuum, as before, was left in the still. A part of the alcohol thus obtained was then rectified, and afterwards afforded a fine ether of specific gravity 0.752. A gallon of the Liverpool naphtha was then distilled with a rectifying apparatus of Dr. Ure's own invention; and a portion of the alcohol obtained from it was made into twenty ounces of ether, of sp. gr. 0.742. This is lighter, and therefore finer, than the standard ether of the Pharmacopœia.

Dr. Ure finds that when ten parts of wood-naphtha are mixed with ninety of alcohol, and the mixture is treated with sulphuric acid, it does not afford ether, but a pungent and offensive fluid, thus showing that the Liverpool mixture contained little or no real naphtha, but owed its peculiar taste and flavour to the pyroligneous oil of the wood-vinegar.

Dr. Ure and Mr. Scanlan were equally successful in making sweet spirit of nitre, and gin, with the rectified Liverpool liquor.

They afterwards ascertained that the pretended naphtha consisted of seventy parts of alcohol, 14.3 above proof, and thirty of pyroligneous acid.

They then tried a variety of experiments with genuine naphtha from the manufactory of Messrs. Hill, of Deptford, and proved, if more proof were needed, how different was the reality from the Liverpool fiction. Among other differences, Hill's naphtha of sp. gr. 0.870 boils at 144° Fah., while

alcohol of the same specific gravity boils at 180°.

Besides these chemical proofs to shew that the casks at Liverpool did not contain naphtha, Dr. Ure gives a commercial one, which is worth mentioning. The casks were imported from New York. Now naphtha is made only from pyroligneous acid; and where there are no great calico-printing establishments (as there are none in the United States) little or none of this acid is prepared. But the casks in question contained about 2000 gallons of "naphtha," equivalent to about 200,000 of pyroligneous acid, "a quantity certainly far greater than has been made there since the days of Elizabeth." The simple fact is, that coarse ardent spirit is excessively cheap in the United States, and pyroligneous acid can easily be procured to give it a flavour.

It appears, moreover, that this same introduction of alcohol, under its masquerade name of naphtha, has become very frequent of late; sometimes it comes from abroad, and at other times it is of native growth.

A sample of some "naphtha" imported from Havre in the "James Watt" was analysed by Dr. Ure, and found to contain at least 95 per cent. of alcohol of sp. gr. 0.842, or about 53.7 over proof!

Ten more samples of sham naphtha were sent to Dr. Ure for analysis, by the fiscal authorities, within one fortnight. Two came from the Customs, and eight from the Excise. The first of the former was an approach to the genuine stuff, and, as Dr. Ure pleasantly

supposes, was intended as a puzzle for our professors of chemistry; for it consisted of sixty parts of real wood-spirit and forty of alcohol. The eight samples seized by the Excise were nothing but alcohol impregnated "with the *dead* coal oil of the coal-tar distillers."

It would be unjust to conclude without mentioning that Mr. Brande made the *amende honorable* in the handsomest manner, and allowed that he had committed an error, in the tone that befits a gentleman.

We have assumed that Dr. Ure is in the right; but should arguments or facts appear to show that he is in the wrong, we shall not let them drop without notice. The only fault we have to find with him at present is that he treats his opponents with a *little* too much asperity. It is obvious, however, that his discovery is of high importance: were the nation served by many men as zealous and as skilful as Dr. Ure, the income tax would have been unnecessary.

EXAMINATION OF THE BODY OF THE LATE MR. TYRRELL.

56 HOURS AFTER DEATH.

Chest.—The pleura closely adherent throughout the whole of the right side of the chest, by old adhesive bands. On the left by a few only.

The right lung hepatised, or consolidated, nearly throughout its whole extent; there being only a very small portion that was crepitant on pressure. The mucous membrane of the lower portion of the trachea and right bronchus thickened, and of a dark brick-dust hue. Left lung engorged with blood, but crepitating tolerably on pressure.

The pericardium considerably distended, and containing from an ounce and a half to two ounces of dark fluid blood. On the posterior aspect of the right auricle the investing pericardium, to a considerable extent, had a rough, depressed, and by the aid of a lens, an ulcerated appearance; while the

* During these and other researches, Dr. Ure had the good fortune to discover the solution of the following problem: as he does not give the solution, we enunciate the difficulty, for the diversion of chemical experimentalists:—"Given a mixture of wood-naphtha and alcohol, each of the same specific gravity, or otherwise, and which suffer no change of density by admixture; to determine, in the course of twenty minutes, the proportion of each."

The problem is solved without the aid of heat.

opposite surface of the loose pericardium, to the same extent, had a granular or tuberculated appearance, very similar to the tuberculous accretions which we find occasionally on the peritoneum; there were two or three adhesive bands connecting these two surfaces.

The heart itself was twice the natural size; the muscular fibre pale, flaccid and flabby, and collapsing; the cavities of both ventricles much dilated, but without hypertrophy of the walls; the left ventricle more especially dilated; in the right ventricle were two or three delicate filaments of lymph of considerable strength, stretching between the *carneæ columnæ* and *chordæ tendineæ*, and across the cavity, the evident result of former endocarditis. All the valves of the heart and aorta were perfectly natural.

The liver was enlarged, very much indurated, especially at the superior portion of the right lobe, and granular throughout.

THE PRESIDENT IN THE CHAIR.

A few Observations on Encysted Hydrocele.

By ROBERT LISTON, F.R.S. Surgeon to the North London Hospital.

THE author commenced by referring to the excellent manner in which the subject had been treated of by former writers, both ancient and modern, and stating, as an apology for introducing it, that he had recently made an observation which induced him to believe that some collections in the scrotum are more intimately connected with the testicle, or its seminiferous tubes, than has been generally supposed. When swellings of this kind have attained a large size, it is difficult, if not impossible, to distinguish between the encysted and the common hydrocele; so that it is only when we have the opportunity of examining them at an early stage of their formation, that we can ascertain their nature correctly. He adverted to the description given by several authors of

eminence, of cysts formed in immediate proximity to the testis or epididymis; and pointed out some of the principal characters by which encysted hydrocele is distinguished from collections in the tunica vaginalis. One peculiarity of the former is, that the fluid contained in it is clear and limpid, and exhibits no traces of albumen; and another is, that in the operations for radical cure its walls are not so prone to take on inflammatory action as those in common hydrocele. One object of the author's communication was to give a rational explanation of this circumstance.

About nine or ten months since he was consulted by a gentleman beyond the middle period of life, on account of tumor of the scrotum. There was plainly fluid on both sides. The largest cyst was punctured, and gave exit to some eight or nine ounces of thin fluid, resembling distilled water with a little soap diffused through it. The other side was punctured a few months afterwards, and five or six ounces of ordinary serum discharged. A short time since the patient returned, to have the first cyst again emptied. The fluid had the same appearance as before; it contained scarcely a trace of albumen. On the second day after it had been drawn off a small quantity was examined with the microscope, when it was found quite full of spermatozoa. It contained also some of the primitive cells in which the spermatozoa are developed, and mucous globules. Had the fluid been examined sooner, probably the animalcules might have been found in motion.

The preceding observation was lately confirmed by the examination of the fluid withdrawn from a small cyst in the scrotum of a man æt. 53, who had applied to be treated for bad stricture. It was nearly transparent, and colourless; and was found to contain numerous spermatozoa, some of which continued to move actively for a considerable time after the fluid had been drawn from the cyst.

The author referred next to several preparations of cysts connected with the body of the testis and epididymis, which he had attentively examined, with the view of ascertaining if possible the nature of the connection between these collections of fluid and the glandular structure of the testis. He concluded with proposing the three following questions for investigation:—

1st, Does the limpid fluid drawn from cysts of the scrotum, or inguinal region, uniformly, or often, contain spermatozoa?

2d, What connection subsists between the seminiferous tubes and these cysts?

3d, Whether dilatation of parts of the epididymis or vas deferens, from obstruction or otherwise, may not in some instances give rise to these collections?

If it be established that these cavities are always lined by mucous membrane, we should have an easy solution of the difficulty regarding a radical cure not following injection, as in the serous cyst.

Some account of an Epidemic which prevailed at Teheran in the months of January and February 1842. By C. W. BELL, M.D. attached to H. B. M.'s Mission at the Court of Persia, in a letter to his Brother, Dr. G. J. BELL, Travelling Fellow of Oxford.

The disease described by the writer occurred nearly simultaneously with an analogous complaint, presenting symptoms like those of angina pectoris, which broke out as an epidemic at Baghdad, and carried off many persons suddenly. The disease which the author witnessed was attended with a nervous excited action of the heart and arteries, periodical, but neither preceded by chill, nor succeeded by perspiration. Many of the patients were seized with fits, which in some instances resembled epilepsy, and in others were like apoplexy, with palsy of one or other of the extremities; in some cases the patients suffered only from numbness and sleeping of the hands and feet, and they had always more or less palpitation of the heart at the same time, sometimes amounting to pain. The attacks of spasm and loss of power in the extremities returned periodically in some instances, but passed off as single attacks in others. The author was induced at first to employ antiphlogistic measures; but these he soon abandoned, and had recourse to quinine. This last medicine he did not find so effectual as a combination of iron and *assafoetida*, which he gave on first accession of the disease, and commonly with speedy success. Numerous cases are related to illustrate the disease and its treatment.

ON ELECTRO-PUNCTURE IN THE TREATMENT OF DEAFNESS, DEPENDING ON A PARALYSIS OF THE ACOUSTIC NERVE.

BY M. JOBERT.

THE paralysis of the acoustic nerve may be produced by exposure to a current of air, to too great a shock of the head, to waves of sound too violent, to affections of the teeth or of the gums. Electro-puncture has been already employed in these cases, but it had fallen into disrepute. The author believes that he uses it in a manner more direct and more rational; here is his proceeding:—Stard's sound, he says, is introduced through the nasal fossa into the eustachian tube, and in this sound a long thin acupuncture needle is inserted, so as to fix itself in a point of the *parietes of the eustachian tube*, while the

other end projects from the end of the sound; another acupuncture needle is implanted in the membrane of the tympanum. This being done, one of the conducting wires of a galvanic battery, of which the trough is filled with water and muriatic acid, is passed through the eye of one of the needles, and the end of the other conducting wire is made to touch the opposite needle. I have used, in the beginning, eight pairs of the battery, then I got to ten, to twelve pairs; finally I have been as high as eighteen, and at present I have patients who have undergone several sittings, and on whom I have acted with the entire pile, the trough of which contains forty metallic pairs. At the moment that the two poles are put in contact, there is a very painful shock in the ear and in the head, with convulsive motions; but this shock and this pain cease immediately. In a single patient the impression was felt during eight days, but it never extended beyond a slight pain, which ceased of itself. It must be added, that the patients who were submitted to electricity in this manner, were, during some moments, as if stunned, and preserved some time after the experiment a bewildered look. The sitting was usually confined to a single shock when the patients were irritable; I have given two and even three shocks in people whose sensibility was obtuse, and who have been already submitted to electro-puncture. In general I allow eight days to pass between each trial. The author then relates four cases of well marked deafness, and in which the cure was complete; in the first after a single shock, in the second after two shocks, and in the third after two sittings, each composed of three galvanic shocks. — *L'Examineur Medical*; and *Dublin Journal*.

LUXATION OF CERVICAL VERTEBRÆ.

PROF. HORNER presented to the class an example of recent occurrence of this rare and commonly fatal accident. A boy, Thomas Brierly, aged ten years, in clambering about an unfinished house, towards the latter part of November, missed his footing on the second floor and fell through the stairway to the cellar, head foremost, a distance of twenty feet. He was stunned by the fall, and was found, as stated by the friends, with his head bent under his body. He was conveyed senseless and motionless to his home. He gradually regained his perceptions, but in an incoherent and perplexed manner: his head was much bruised by the fall, his neck was stiff and distorted, forming a large serpentine bulge on the left side, and a deep concavity to the right: his face was inclined downwards to the right side. Circumduc-

tion of the head was arrested and the neck motionless. The practitioner, Dr. Henry, who attended him in this stage of the injury, applied leeches to the part, emollients and frictions in succession.

In two days after the accident his common and accurate perceptions returned, but he was affected for some time with tingling and numbness in the left upper extremity.

At the period of his exhibition to the class the deformity of the neck is still obvious, but much reduced; the rotatory motions of the neck can now be executed to some extent, but are much more to the right than to the left side. On tracing the line of the transverse processes of the vertebræ, the upper ones starting from the fourth are about half an inch forward of the lower, indicating clearly the advance of the vertebra on that side, and consequently proving that the left lower oblique process of the fourth vertebra had been luxated in advance of the upper oblique of the fifth, and was there fixed.

We may presume from this state of the accident, that the intervertebral substance there had been partially or wholly ruptured, and that the two vertebræ were held together by the other ligamentous attachments and by the muscles. An attempt at the replacing of such a luxation is viewed with great apprehension by surgeons. Desault, in a case analogous, absolutely declined making the effort, for fear of its fatal issue; and it is related by M. Petit Radet, (Boyer, *Malad. Chir.* vol. 4, p. 118,) that a young patient at La Charité expired in the hands of the surgeons, upon such an attempt a few days after the accident. This result is very intelligible when we reflect that to disengage an oblique process thus placed, it is necessary to begin by increasing the inflection forwards, or in other words, by augmenting the displacement, which must in all probability tear up more of the natural fastenings of the bones, and thus subject the spinal marrow to compression or even laceration. Under these circumstances Brierly was dismissed with some general directions for his treatment, and the expectation that his youth would insure a still further erection of that part of the spine. At the period of his exhibition, say about six weeks after the accident, his general health was good, he enjoyed the use of all his faculties, and was going to school.—*American Medical Examiner*, Jan. 21, 1843.

LECTURES
ON THE
**THEORY AND PRACTICE OF
MIDWIFERY,**

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE XXIX.

On the operation of craniotomy, the induction of premature labour, and the Cæsarean section.

WHERE the child is dead, where a great disproportion exists between its head and the pelvis from any cause, and the os uteri is imperfectly dilated, and the parts swollen and rigid, and an ear cannot be felt, and circumstances occur demanding immediate delivery, recourse must be had to the perforator, and not to the forceps. It is in difficult labour from distortion of the pelvis that we are most frequently compelled to open and extract the head; and where this exists in a high degree, and the brim is so contracted that the head cannot enter it, the operation of craniotomy often requires the employment of strong extracting force for several hours; and fatal contusion and laceration of the uterus, vagina, bladder, and rectum, can only be prevented by the greatest caution and dexterity, and a perfect knowledge of the structure of all the parts. It unfortunately happens that, in some cases, before the operation is performed, the soft parts have already been injured by the long-continued pressure they have sustained,—the same thing happens here which takes place in strangulated hernia, where the operation has been delayed too long,—and sloughing follows. In cases of slight disproportion between the head and pelvis, or where there is none, but delivery becomes necessary in consequence of convulsions,

810.—XXXII.

hæmorrhage, or exhaustion, the operation is attended with little difficulty and danger; much less than the application of the forceps. The position of the patient ought to be the same—the left side, near the edge of the bed—whether you are going to use the forceps, perforate the head, induce premature labour, deliver by turning the child, or remove a retained placenta. The difficulty of all these operations will be greatly increased if you allow patients to lie upon the back, as they do during labour on the Continent, or on the left side at a distance from the edge of the bed. No practitioner, whatever the extent of his experience may be, ought, in my opinion, to open the head of a child, without the most urgent necessity, unless he is absolutely certain that the child is dead, before consulting another accoucheur. Where the bladder is distended with urine, and the urethra is much pressed upon by the head of the child, you will introduce the catheter more easily and safely after the head has been lessened than before perforation.

If the head is in the cavity of the pelvis, or the greater part of it has passed through the brim, and it is not impacted, and the os uteri is fully dilated, no difficulty can be experienced in perforating and extracting the head. With the fore-finger of the right hand carefully examine the situation of the head; and if you can feel a suture or fontanelle, let the point of the perforator pass into it; but if the head is much swollen, and you cannot distinguish either of these, resolve to open the head in the most depending part; and if the instrument is of sufficient strength, it will pass without much difficulty, even through the centre of either of the parietal bones. Having with the fore-finger of the right hand determined the point where the perforator is to enter, slide up the fore and middle fingers of the left hand, before withdrawing the fore-finger of the right, to this point; and in the groove formed between these fingers of the left

hand, slowly and carefully introduce the perforator, previously warmed; and when it has reached the head, press it firmly forward, during a labour pain, through the integuments and bones, as far as the rests will permit it to go, by a boring or semi-rotatory motion. Where a great effusion is formed under the scalp, if the instrument is

not driven forward with sufficient force, you will open the tumor of the scalp without opening the skull, as I have seen happen more than once, to the annoyance of practitioners. When the perforator has been introduced, in the manner represented in the following figure, withdraw the fingers of the left hand, while with the right you keep the

instrument from receding. If you remove the pressure with the right hand from the handles at this time, the point will escape from the head, and the skull, if perforated at all, will not be so to a sufficient extent to enable you afterwards to use the crotchet.

Having by firm pressure prevented this accident, take hold of one of the rings of the handles of the perforator with your left hand, and the other with the right, and draw the handles widely asunder, and at the same time press the handles forward, that

the points may not slide back from the head. Having made a large lacerated opening in the integuments and bones, close the handles, and with the fore-finger of the left hand ascertain that the points are still within the head as far as the rests, and then turn the handles round about a quarter of a circle, and open them slowly, with the same precautions, and to a similar extent. Having made a large crucial incision, pass the perforator within the skull, and turn it freely around in every direction until the brain is completely disorganized, and a considerable portion of it has escaped. It is right to do this effectually, and to allow an interval of a quarter of an hour or longer to elapse, that more of the brain may escape, and the bones collapse, before attempting to extract the head with the crotchet. All syringes and instruments for scooping out the brain are quite unnecessary. Then, in your right hand, take the handle of the common crotchet, which should neither be very sharp nor very blunt in the point, and with the fore and middle fingers of the left hand introduce it through the opening in the head, and still more completely destroy the texture of the brain, and draw out as much of it as you can through the opening. Then fix the point of the crotchet on the inside of the head behind—I mean on the part which corresponds with the hollow of the sacrum, at as great a distance as possible from the opening in it made with the perforator, and pass up the fore and middle fingers of your left hand between the posterior wall of the vagina and the head, till their extremities are exactly opposite to the part where the point of the instrument is fixed within. When a pain comes on press the point of the crotchet against the bone, laying firm hold of its handle with your right hand, while you press firmly the points of the fingers of the left hand on the outside of the head, and at the same time turn the ring and little fingers of this hand around the handle, or rather shank, of the crotchet, close to the orifice of the vagina. In this manner you form a double crotchet, far more safe and powerful than that which was invented by Smellie [exhibiting it], which has fallen into complete disuse, because it tore the bones and integuments to pieces, but did not extract the head. With the crotchet fixed on the inside of the bones of the head behind on the part lying in the hollow of the sacrum, and the fore and middle fingers of the left hand on the outside, and with the other two grasping the shank of the crotchet, you can exert a great degree of extracting force, and you will often succeed in completing the delivery in a short period if the perineum is not rigid. The head should always be drawn backward till

the perineum is put upon the stretch, and to prevent the bones from being torn, and the hold with the crotchet lost, the traction should be made slowly and steadily, and during the pains, and time given for the parts to dilate. But if there is any considerable obstruction to the head, however carefully the extracting force may be applied, the point of the crotchet will tear away the bone upon which it is fixed, and it must be placed upon another part of the bones of the head; or you may lay aside the crotchet altogether, and employ the craniotomy forceps, which undoubtedly does in some cases possess advantages over the crotchet. If you know how to form the double crotchet which I have described, and which is one of the most safe and powerful weapons in midwifery, and most frequently sufficient to complete the delivery without any other means, the mother is exposed to no danger from laceration of the bones of the head and slipping of the crotchet, for the point of the instrument is constantly covered with the extremities of the fingers, and the two hands never act but in concert. But where the bones are readily torn, and you are compelled repeatedly to seek a fresh hold, and perhaps meet with some difficulty in fixing the instrument again, I would recommend you to lay aside the crotchet, and try the craniotomy forceps, which is represented in the following figure, the blades of which resemble somewhat the jaws of a crocodile, and which I have employed satisfactorily in many cases of difficult labour from distortion of the pelvis and other causes. The lock is the same as the lock of the common forceps, and the blades are likewise introduced separately and then brought together and fixed. One

hand, slowly and carefully introduce the perforator, previously warmed; and when it has reached the head, press it firmly forward, during a labour pain, through the integuments and bones, as far as the rests will permit it to go, by a boring or semi-rotatory motion. Where a great effusion is formed under the scalp, if the instrument is

not driven forward with sufficient force, you will open the tumor of the scalp without opening the skull, as I have seen happen more than once, to the annoyance of practitioners. When the perforator has been introduced, in the manner represented in the following figure, withdraw the fingers of the left hand, while with the right you keep the

instrument from receding. If you remove the pressure with the right hand from the handles at this time, the point will escape from the head, and the skull, if perforated at all, will not be so to a sufficient extent to enable you afterwards to use the crotchet.

Having by firm pressure prevented this accident, take hold of one of the rings of the handles of the perforator with your left hand, and the other with the right, and draw the handles widely asunder, and at the same time press the handles forward, that

the points may not slide back from the head. Having made a large lacerated opening in the integuments and bones, close the handles, and with the fore-finger of the left hand ascertain that the points are still within the head as far as the rests, and then turn the handles round about a quarter of a circle, and open them slowly, with the same precautions, and to a similar extent. Having made a large crucial incision, pass the perforator within the skull, and turn it freely around in every direction until the brain is completely disorganized, and a considerable portion of it has escaped. It is right to do this effectually, and to allow an interval of a quarter of an hour or longer to elapse, that more of the brain may escape, and the bones collapse, before attempting to extract the head with the crotchet. All syringes and instruments for scooping out the brain are quite unnecessary. Then, in your right hand, take the handle of the common crotchet, which should neither be very sharp nor very blunt in the point, and with the fore and middle fingers of the left hand introduce it through the opening in the head, and still more completely destroy the texture of the brain, and draw out as much of it as you can through the opening. Then fix the point of the crotchet on the inside of the head behind—I mean on the part which corresponds with the hollow of the sacrum, at as great a distance as possible from the opening in it made with the perforator, and pass up the fore and middle fingers of your left hand between the posterior wall of the vagina and the head, till their extremities are exactly opposite to the part where the point of the instrument is fixed within. When a pain comes on press the point of the crotchet against the bone, laying firm hold of its handle with your right hand, while you press firmly the points of the fingers of the left hand on the outside of the head, and at the same time turn the ring and little fingers of this hand around the handle, or rather shank, of the crotchet, close to the orifice of the vagina. In this manner you form a double crotchet, far more safe and powerful than that which was invented by Smellie [exhibiting it], which has fallen into complete disuse, because it tore the bones and integuments to pieces, but did not extract the head. With the crotchet fixed on the inside of the bones of the head behind on the part lying in the hollow of the sacrum, and the fore and middle fingers of the left hand on the outside, and with the other two grasping the shank of the crotchet, you can exert a great degree of extracting force, and you will often succeed in completing the delivery in a short period if the perineum is not rigid. The head should always be drawn backward till

the perineum is put upon the stretch, and to prevent the bones from being torn, and the hold with the crotchet lost, the traction should be made slowly and steadily, and during the pains, and time given for the parts to dilate. But if there is any considerable obstruction to the head, however carefully the extracting force may be applied, the point of the crotchet will tear away the bone upon which it is fixed, and it must be placed upon another part of the bones of the head; or you may lay aside the crotchet altogether, and employ the craniotomy forceps, which undoubtedly does in some cases possess advantages over the crotchet. If you know how to form the double crotchet which I have described, and which is one of the most safe and powerful weapons in midwifery, and most frequently sufficient to complete the delivery without any other means, the mother is exposed to no danger from laceration of the bones of the head and slipping of the crotchet, for the point of the instrument is constantly covered with the extremities of the fingers, and the two hands never act but in concert. But where the bones are readily torn, and you are compelled repeatedly to seek a fresh hold, and perhaps meet with some difficulty in fixing the instrument again, I would recommend you to lay aside the crotchet, and try the craniotomy forceps, which is represented in the following figure, the blades of which resemble somewhat the jaws of a crocodile, and which I have employed satisfactorily in many cases of difficult labour from distortion of the pelvis and other causes. The lock is the same as the lock of the common forceps, and the blades are likewise introduced separately and then brought together and fixed. One

blade is introduced within the head, and the other on the outside, with the same caution as the second blade of the common midwifery forceps. The ragged edges of the bones should be covered with the integuments before you begin to extract, and in operating with the crotchet it is of great importance frequently to pass the finger around the opening in the head, to ascertain if there is not some sharp and uncovered portion of bone pressing against the vagina. When the craniotomy forceps is applied so as to include a large portion of the integuments and bones of the head, the hold you obtain with it is very secure, and you may not only exert a much greater degree of force than you could employ with the crotchet, but you can accommodate the head much better to the axis of the outlet of the pelvis, and protect the perineum, which is exposed to great danger from laceration in all cases of craniotomy. When the head is drawn entirely forward out of the vagina with the crotchet, the perineum must, as you require both hands to wield the instrument, be supported by an assistant, who cannot know the degree of force which you are exerting at any time. If the craniotomy forceps be employed, you can support the perineum with your left hand, while you are operating with the right and drawing the head forward toward the pubes. With the forceps the perineum is certainly exposed to less risk than with the crotchet, but I admit that it may be seriously injured with the forceps if it be a first child, and the bones of the head, compressed into a shape like a wedge, are drawn hastily forward.

In cases of great distortion, where the head cannot enter the brim of the pelvis to any extent, and the os uteri is imperfectly dilated, there is no instrument after perforation so efficient—none to be compared with the crotchet. I have tried all varieties of craniotomy forceps in such cases, and can assure you that they are totally inapplicable unless the os uteri is widely dilated and the head has made considerable progress through the brim into the cavity of the pelvis. M. Baudelocque has invented a huge instrument, weighing four pounds, for crushing the head in these cases, called *céphalotribe* [exhibiting a figure of it], but it cannot be applied to the head above the brim of the pelvis, and if the os uteri is undilated. In M. Baudelocque's cases the effects of injurious pressure were striking, and they would probably have been much slighter had the perforator and crotchet been employed. Great care must be taken in perforating the head in cases of extreme distortion, that the os uteri is not wounded with the sharp edges of the instrument. To obviate this, if the outlet is not so much contracted as to prevent the

hand from being introduced, the fore and middle fingers of the left hand, or all the fingers, should be passed up within the os uteri to the most depending part of the head, and the opening made in the same manner as already described, while the orifice is protected by the fingers expanded. The undilated state of the uterus adds greatly to the difficulty. In extracting the head with the crotchet, it not unfrequently happens that the bones of the cranium are all torn to pieces, and removed, before the base of the skull has entered the brim of the pelvis. It is impossible, under such circumstances, to fix the point of the crotchet in the foramen magnum, as some recommend; and the best mode of proceeding is to pass the fingers of the left hand over the head as far as possible, and to slide up the crotchet between the fingers and the outside of the head, and fix its point in one of the orbits, about the angles of the lower jaw, or wherever a secure hold can be obtained. In this manner, as recommended by Smellie, I have sometimes succeeded in extracting the head in a short time, where I had begun to despair of ever doing so by fixing the crotchet on the inner surface of the base of the cranium, or by any other means. Indeed, in cases of this description you must be prepared to encounter very great difficulties; but when you look at this distorted pelvis from malacosteon, which measures only $1\frac{1}{2}$ inches from the last lumbar vertebra to the symphysis pubis, and know that two children, at the full period, were drawn through it without destroying the mother, you may conclude that few cases of distortion can possibly occur where you will not ultimately succeed in effecting the delivery with the crotchet. What the degree of distortion is which renders the operation of craniotomy impossible I am unable to state; what is impossible to one may not be so to another practitioner possessed of greater power, dexterity, and patience.

In this table (see pp. 375-8) the results are contained of 127 cases of difficult labour in which it was necessary to deliver by opening the head. After carefully examining all the details of these cases, I feel satisfied that in none was the interference premature, and that in several had the delivery been sooner effected the fatal consequences which ensued would have been prevented. I do not believe there is one of these cases in which the operation was resorted to without a consultation, and the necessity and propriety of the measure fully admitted.

On the Induction of Premature Labour.

The history of this operation, which is the greatest improvement in midwifery since the invention of the forceps, was first given by Dr. Denman about 1795. "We have before

alluded," he says, "to this operation as a method of preserving the lives of children, without adding to the danger of women; if in any case the pelvis were so much distorted, or so small, as absolutely to prevent the passage of the head of a full-grown child, and yet not so far reduced in its dimensions as to prevent the head of a child of a much less size from passing through it. Melancholy are the reflections, where a woman has a very much distorted pelvis (and such women have usually wonderful aptitude to conceive) that there should be little, if any, chance of preserving the lives of their children; and yet, in the course of practice, I have in several instances been called to the same woman in five or six successive labours, merely to give a sanction to an operation by which the children were to be destroyed. It is to the credit of the profession that every method by which the lives of parents and children might be preserved has been devised and tried: and though frequent occasions for using some of these methods cannot possibly occur in any one person's practice, it is right that all should be acquainted with what has been proposed and done in every case, with or without success.

"The first account of the method of bringing on premature labour was given to me by Dr. C. Kelly. He informed me, that about the year 1756 there was a consultation of the most eminent men in London at that time, to consider of the moral rectitude of, and advantages which might be expected from, the practice, which met with their general approbation. The first case in which it was deemed necessary and proper fell under the care of the late Dr. Macaulay, and it terminated successfully. (The patient was the wife of a linen-draper in the Strand.) Dr. Kelly informed me that he himself had practised it, and, among other instances, mentioned that the operation had been performed three times upon the same woman, and twice the children had been born living. The thing has often been the subject of conversation, and proposed by writers, but some have doubted the morality of the practice; and the circumstances which may render the operation needful and proper have not been stated with any degree of precision."

The morality, perfect safety, and the utility of the operation, have been fully established, not only in cases of distorted pelvis, but in some of the dangerous diseases of pregnancy, by the experience of all the most eminent practitioners in Great Britain during the last 87 years, and I do not know that it has often, if ever, been employed for criminal purposes in this country. In cases of slighter distortion recourse

should not be had to this operation until it has been proved by one or more labours that a child at the full period would not pass without lessening the head. Labour should not be brought on until the $7\frac{1}{2}$ month of gestation, or a little later, where it is known

that the pelvis is very little contracted. In cases of very great distortion of the pelvis, the induction of premature labour at an early period, even of the first pregnancy, (as has already been stated, before the sixth month,) is likewise known to be a safe operation, and to render craniotomy and the Cæsarean section wholly unnecessary. The only effectual method of bringing on premature labour is to puncture the foetal membranes and discharge the liquor amnii. I have repeatedly detached the membranes with a catheter from the lower part of the uterus, but labour has not followed. I have strong objections to the exhibition of ergot for the purpose of inducing premature labour, without taking the uncertainty of its effects into account. I have successfully employed this probe-pointed catheter

(represented in the figure above), with a stilette in many cases to puncture the membranes, when I could not do so with instruments less curved and having sharp points.

When you are about to induce premature labour, pass up the fore-finger of the right hand to the os uteri, and when you have ascertained its precise situation slide up along this finger the fore and middle fingers of the left hand to the posterior lip; the points of the fingers should if possible touch the posterior lip; then withdraw the fore-finger of the other hand, and take the handle of the instrument with it, and pass up the point in the groove formed between the fingers of the left hand to the os uteri, and gently press it forward along the cervix into the cavity of the uterus, about $1\frac{1}{2}$ or 2 inches, when the membranes will generally be felt offering a slight degree of resistance. The stilette should then be pressed forward with the thumb, and a second puncture made through the membranes before withdrawing the instrument. The blunt point of this catheter enables us to pass it into the uterus with safety, where the os uteri is so high up that the finger cannot even reach the anterior lip. When the liquor amnii has escaped, labour follows, and if the presentation is natural no peculiar treatment is required.

I have been informed that some accoucheurs on the continent induce premature labour by forcing a piece of sponge into the

os uteri, which I consider very objectionable. Uterine contractions might be excited, it was stated to me last year by a German physician, without forcing the sponge into the os uteri—by simply pressing it into the upper part of the vagina. I have lately had an opportunity of putting this plan to the test, and it completely failed.

On the Cæsarean section.

Having already defined, as clearly as I possibly can, the cases of difficult labour in which it is justifiable to employ this method of delivery, I have nothing further to say on the subject. I have never seen the operation performed on the living body. On the dead body it is not a difficult matter, for the gravid uterus is at once brought into view by a long incision through the abdominal parietes in the direction of the linea alba. But the child soon dies after respiration has ceased in the mother.

When Dr. Hull, of Manchester, performed this operation on a woman with distorted pelvis, he made a transverse incision nearly six inches in length, and higher than the umbilicus, in the right side of the abdomen, to which part the fundus uteri was inclined, through the integuments, muscles, and peritoneum. He then made an incision of the same length and in the same direction through the parietes of the uterus, and with great ease and expedition extracted a child which had been dead for some days. The placenta was extracted at the wound without any difficulty. The intestines now began to protrude at the wound, and it was not without a great deal of attention and trouble that they were reduced and retained in the cavity of the abdomen, whilst he stitched the external incision by means of the uninterrupted suture, carefully avoiding the peritoneum. The quantity of blood lost during the operation did not exceed 3 or 4 ounces, and no artery was divided that required a ligature, or any application made to it for the purpose of restraining hæmorrhage. The patient died.

Graefe performed the operation at least once successfully. The time of operation, he says, should if possible be that of natural labour; the place of the incision the linea alba: but if the uterus does not lie in the middle of the abdomen, and cannot be brought there, the incision must be carried in a line over the foetus. To prevent protrusion of the intestines they must be carefully removed from the face of the uterus, and fixed with three warm sponges, each a foot long and six inches wide, so as to leave a free space 8 inches long and four broad for an incision of 9 French inches in length through the abdomen, and of $4\frac{1}{2}$ through the uterus. In

dressing the wound three sutures and circular plasters should be used.

Mr. Knowles has related a successful case of Cæsarean section in the fourth volume of the Provincial Medical and Surgical Association. The woman was 36 years of age, and had been delivered of several living children. During a pregnancy in 1829 she had pains in the hips and loins, with loss of power in the lower extremities. She miscarried after this several times. In her ninth pregnancy Mr. Knowles was called to see her on the 15th May, 1835, labour having commenced about 4 P.M. of the 14th. The sacrum, with the lower lumbar vertebra, projected, and at the same time descended far into the cavity of the pelvis, and occupied a large portion of it, and resembled the child's head. The ossa pubis were bent inwards so much that they approached very near to the distorted vertebræ. The presentation could not be ascertained. The space left by the deformity did not exceed two inches in length by less than one in breadth. The head could not be felt, and therefore could not be opened. The Cæsarean operation was performed by Mr. Knowles 30 hours after the commencement of the labour; the external incision, about ten inches in length, was made through the linea alba immediately on the left side of the umbilicus. A portion of intestine immediately protruded. The incision into the uterus was commenced near its fundus by passing the scalpel carefully through its parietes, which were about an inch in thickness, so as to allow the admission of two fingers: using the fingers as a director, the opening was rapidly enlarged, by which the placenta was exposed and a brisk hæmorrhage produced. Passing my hand by the side of the placenta, says Mr. Knowles, I ruptured the membranes, and without difficulty took out the child, which was living. The placenta was then detached, some coagula were removed, the uterus contracted, and the hæmorrhage, which probably did not exceed xxvi. , was arrested. The external integuments were brought together by stitches, which were inserted at somewhat more than an inch apart. Adhesive straps were applied in the intervals, and the whole was secured by a compress and bandage. Tympanites and several alarming symptoms followed the operation. The wound did not heal by the first intention, so that the serous and purulent fluids readily escaped. Had the condition of this woman been known during pregnancy, which probably was not the case, as it is not alluded to in the history, the necessity for the operation would have been obviated altogether by puncturing the ovum in the early months.

A TABULAR VIEW OF ONE HUNDRED AND TWENTY-SEVEN CASES OF DIFFICULT LABOUR

in which Delivery was effected by the Operation of

Craniotomy.

No.	Date.	Causes of Difficulty.	Hours in Labour.	Result.
1	June 28, 1823	1st labour—Impaction of head; small pelvis; swelling of soft parts: long forceps	72	Recovered—Vesico-vaginal fistula.
2	July 12, 1823	1st labour—Rigidity, exhaustion, convulsions: long forceps	50	Recovered—Uterine inflammation.
3	July 28, 1824	1st labour—Pelvis and extremities distorted by rickets	67	Recovered—Uterine inflammation.
4	August 1, 1824	Face presentation	58	Recovered.
5	October 29, 1827	9th labour—Uterine hæmorrhage from detachment of placenta	12	Died—Inflammation of uterus.
6	Nov. 2, 1827	1st labour—Distortion of pelvis; head and arm presenting; child dead	72	Recovered—Uterine inflammation.
7	Dec. 3, 1827	Distorted pelvis; arm presentation with head; turning; head impacted	90	Recovered—Severe inflammation.
8	Feb. 29, 1828	1st labour—Head impacted many hours; retention of urine; great exhaustion	36	Recovered.
9	March 2, 1828	3d labour—Head fixed in brim; great exhaustion; extraction difficult	40	Recovered.
10	March 12, 1828	Hydrocephalus of foetus; dropsy of amnion; sixteen pints liquor amnii	30	Died—Uterine inflammation.
11	April 3, 1828	1st labour—Distorted pelvis; prolapsus of cord; swollen and tender vagina	84	Recovered.
12	May 9, 1828	1st labour—Convulsions; rigidity [brim; cord prolapsed	—	Recovered.
13	July 3, 1828	1st labour—Distortion of inlet and outlet of pelvis; head and foot impacted in	24	Recovered—Severe inflammation.
14	August 6, 1828	Enormous œdema of thighs and external parts; a large exomphalos	24	Recovered.
15	Sept. 19, 1828	Swelling of scalp; head impacted; pains feeble	48	Recovered.
16	Nov. 5, 1828	Uterine hæmorrhage from detachment of placenta	21	Died—Hæmorrhage.
17	Nov. 18, 1828	Distortion of pelvis; regular labour pains	48	Recovered—Uterine inflammation.
18	Dec. 16, 1828	Impaction of head; retention of urine; abdomen tense and painful; delirium	48	Recovered.
19	Feb. 4, 1829	2d labour—Head swollen, and impacted in brim of pelvis	48	Recovered—Uterine inflammation.
20	March 27, 1829	1st labour—Rigidity; impaction; exhaustion; delirium; lacerated perineum	72	Died—Sloughing.
21	April 29, 1829	1st labour—Cessation of uterine contractions; head fixed in brim; bladder distended	144	Recovered.
22	July 14, 1829	Hydrocephalus of foetus; dropsy of amnion	60	Died—Phlebitis; gangrene of lung.
23	August 18, 1829	Exhaustion; child dead two days	20	Recovered—Recto-vesical fistula.
24	Autumn, 1829	1st labour—Impaction of head; feeble uterine contraction; exhaustion	48	Recovered.
25	September, 1829	1st stage protracted; labia immensely swollen	74	Died—Gangrene of vagina.
26	October, 1829	Induction of labour at 7½ months; distorted pelvis	48	Recovered.
27	Nov. 8, 1829	Distorted pelvis; arm presentation; swollen vagina	20	Died—Laceration of os and cervix uteri.
28	Nov. 18, 1829	Accidental uterine hæmorrhage; rigid os uteri; vomiting; exhaustion	4	Died two hours after delivery.

No.	Date.	Causes of Difficulty.	Hours in Labour.	Result.
29	Dec. 5, 1829	1st labour—Distorted pelvis from rickets	40	Recovered—Uterine inflammation.
30	Dec. 27, 1829	Head impacted in brim; exhaustion	48	Recovered.
31	Jan. 17, 1830	Great distortion of pelvis; exhaustion; os uteri half dilated	50	Recovered.
32	October 30, 1830	Distortion of pelvis; labour induced at 7½ months; arm presentation; turning performed with difficulty; head perforated behind the ear	—	Recovered.
33	Dec. 6, 1830	Head compressed in brim; feeble uterine action; vagina swollen and painful	72	Recovered—Vesico-vaginal fistula.
34	Feb. 17, 1831	Slight distortion; impaction of head; delirium; labour-pains gone	Many	Recovered.
35	March 6, 1831	Tumefaction of labia and vagina; cessation of uterine action	72	Recovered—Sloughing of vagina.
36	March 27, 1831	Exhaustion; inflammation and tumefaction of vagina	72	Recovered—Sloughing and cicatrix.
37	March, 1831	Impaction of head twelve hours; abdomen tender; despondency; restlessness	48	Recovered.
38	April 16, 1831	Impaction of head in brim; exhaustion; perforation in a previous labour	24	Recovered.
39	Dec. 1831	Severe fits; cessation of pains; head above brim	—	Recovered.
40	October, 1831	Deformed pelvis; nates presentation; head impacted	—	Recovered.
41	March 15, 1832	1st labour—Exhaustion; distorted pelvis	50	Recovered.
42	April, 1832	Os uteri rigid; head impacted in brim; distortion; ergot given	60	Recovered.
43	May 9, 1832	Convulsions and unconsciousness for several hours	48	Recovered.
44	July 11, 1832	Distorted pelvis, in the highest degree, from malacosteon	30	Recovered.
45	Sept. 18, 1832	Distortion from rickets in infancy; rigidity; pulse rapid	36	Recovered.
46	Sept. 13, 1832	1st labour—Great distortion of pelvis; extraction difficult	36	Recovered.
47	Sept. 14, 1832	Valvular disease of heart; dyspnoea increased by labour; danger of immediate asphyxia	—	Recovered.
48	October 5, 1832	Highly distorted pelvis; induction of premature labour at 7½ months; nates presentation	72	Died—Uterine phlebitis.
49	— 1832	Head wedged in brim; bladder enormously distended; vagina hot and swollen	—	Died—Inflammation of bladder.
50	April 11, 1833	Impaction of head	30	Recovered.
51	March 30, 1843	Head, left arm, and funis without pulsation	12	Recovered.
52	July, 1833	Distortion of pelvis; shoulders jammed in brim; head nearly separated from trunk	48	Recovered.
53	July 5, 1833	1st labour—Head above brim; great prostration; incoherence	64	Recovered.
54	July 5, 1833	1st labour—No progress for twenty-four hours; delirium	—	Recovered.
55	July 5, 1833	1st labour—Delirium; convulsions	—	Recovered.
56	Nov. 10, 1833	Exhaustion from being allowed to remain too long in labour; abdomen painful; vagina swollen	24	Recovered.
57	Nov. 11, 1833	1st labour—Small pelvis; child large; rigidity	72	Recovered.
58	Dec. 1833	1st labour—Violent convulsions; exhaustion	46	Recovered.
59	Dec. 31, 1833	Incoherence; cessation of pains; swelling of soft parts	16	Recovered.
			72	Recovered.

No.	Date.	Causes of Difficulty.	Hours in Labour.	Result.
96	Jan. 13, 1840	Slight distortion of pelvis; face presentation; head impacted in brim; right labium immensely distended, burst, and great hæmorrhage	Many	Recovered.
97	Feb. 1, 1840	1st labour—Exhaustion; fever	52	Recovered.
98	April 14, 1840	1st labour—Head compressed in brim; rigid os uteri; exhaustion; fever	72	Recovered.
99	May 1, 1840	Malignant disease of os and cervix uteri	24	Died—Ruptured uterus.
100	July 7, 1840	Head firmly fixed in pelvis; exhaustion	48	Recovered.
101	Dec. 31, 1840	1st labour—Exhaustion	40	Recovered.
102	Jan. 12, 1841	Head impacted in brim of pelvis; vagina swelled, and an offensive discharge from it	94	Recovered.
103	Feb. 11, 1841	1st labour—Head impacted; great tumor of scalp; exhaustion	38	Recovered.
104	April 1, 1841	Head, hand, and funis presentation; delirium [lirium	48	Recovered.
105	May 3, 1841	1st labour—Impaction of head; peculiar nervous irritability; exhaustion and de-	34	Recovered.
106	June 13, 1841	Head and right arm presenting; would not allow child to be turned	—	Recovered.
107	Sept. 14, 1841	Head swollen and fixed in brim of pelvis; delirium	72	Recovered.
108	Oct. 14, 1841	Distorted pelvis; incoherence	92	Died.
109	Oct. 30, 1841	Head impacted in brim of pelvis; exhaustion	35	Recovered.
110	Dec. 12, 1841	1st labour—Brim and outlet of pelvis distorted; threatened rupture of uterus	48	Recovered.
111	Jan. 8, 1842	Rigidity; nates presentation; head impacted; child dead	—	Recovered.
112	Feb. 12, 1842	1st labour—Distortion of pelvis from rickets	72	Recovered.
113	June 4, 1842	Exhaustion; thickening of vagina	96	Recovered.
114	June 18, 1842	Hydrocephalus of foetus; rupture of uterus	72	Died.
115	June 20, 1842	Hydrocephalus of foetus; rupture of uterus	22	Died.
116	July 15, 1842	1st labour—Impaction of head; swelling of scalp; exhaustion	60	Recovered.
117	1838	Distorted brim of pelvis; impacted head; swollen vagina; forceps used	48	Died.
118	1830	1st labour—Pelvis small; head impacted in brim; parts rigid	48	Recovered.
119	1836	Violent puerperal convulsions; not relieved by venesection	—	Recovered.
120	1839	Head impacted in brim; soft parts enormously swollen; delirium	—	Recovered—Sloughing of vagina.
121	Feb. 4, 1843	Impaction; great exhaustion	24	Died.
122	Feb. 13, 1843	Uterine action suspended through terror; delirium; V.S.; os uteri undilated	24	Recovered.
123	April 12, 1843	Great distortion of pelvis; 2d labour; 1st child delivered by craniotomy	70	Recovered.
124	May 6, 1843	Great distortion; nates presentation; head perforated behind	30	Recovered.
125	May 31, 1843	Small pelvis; impaction; retention of urine	60	Recovering.
126	May, 1843	Impaction; child dead; vagina swollen and inflamed	60	Recovered.
127	June 1, 1843	Great distortion; has had four dead children, and very protracted labours	24	Recovered.

CLINICAL LECTURES
ON THE
THEORY & MEDICAL TREATMENT
OF INSANITY,

*Delivered at St. Luke's Hospital,
May 1st, 3d, and 5th.*

BY ALEXANDER JOHN SUTHERLAND.

LECTURE II.

Alterations in the blood; pulse; diagnosis between phrenitis and insanity; signs of acute inflammation seldom met with in insanity; congestion, whether active, passive, or mechanical, generally accompanies the disease; hyperæmia; anæmia; alterations in the quality of the blood; M. Couverbe's theory, refuted by M. Frémy; post-mortem examinations; alterations found in the scalp, bone, dura mater, in the cavity and cellular tissue of the arachnoid, in the pia mater; acute and chronic alterations of the cortical

structure, those of the fibrous structure, spinal marrow, nerves; morbid appearances found in the viscera of the thorax and abdomen.

IN my last lecture, gentlemen, I endeavoured to lay before you examples of insanity with lesions of innervation; it is my intention in my present lecture to speak of the disorders met with in the circulating fluid. When a nerve has become exhausted, two things are necessary to restore it to a healthy state: rest from its particular function, and contact with good arterial blood. The state of the circulation, then, the quantity and quality of the blood, are very material points for our consideration. Some practical writers have said that the pulse is not affected in insanity; this does not accord with my experience, as the following table will show, in which the number of pulsations per minute are given, the state of the pulse on admission into the hospital and upon the discharge of the patient, the form of the disease, and the result of the treatment.

The cases are placed in the order in which they come in my note-book, and are not selected.

MEN.			
Pulse on admission.		When discharged.	
Initials	Form of disease.	Result.	Pulse.
1. P.	Melancholia	80	uncured . 64
2. F.	Mania	100	cured . 96
3. M.	Melancholia	64	cured . 120
4. M.	Mania	100, very weak	paralytic . 84 weak
5. B.	Melancholia, Inter- mittent	100	on trial . 88
6. P.	Melancholia	120, weak	cured . 100, stronger
7. F.	Mania	60	on trial . 64
8. G.	Mania	68	cured . 100
9. W.	Mania, Intermittent	120	uncured . 88
10. H.	Mania	120	uncured . 80
11. S.	Catalepsy	100	cured . 84
12. T.	Mania	100 full, intermittent, and regular	cured . 88, not full, inter- mittent
13. E.	Melancholia	100	cured . 80
14. H.	Melancholia	100, weak	uncured . 84
15. S.	Melancholia	100	cured . 100
16. G.	Mania	100, weak	cured . 100, stronger
17. O.	Acute Dementia	100, weak	cured . 88, of good strength
18. H.	General Paralysis	100	paralytic . 108
19. B.	General Paralysis	96	paralytic . 88
20. W.	Melancholia	120, weak	cured . 100, stronger
21. P.	Mania	104	cured . 80, intermitting
22. S.	Mania	100, weak	cured . 88, of good strength
23. S.	Melancholia	64	cured . 80, strong
24. O.	Acute Dementia	92, full	cured . 100
25. H.	Mania	112	cured . 104

WOMEN.			
1. W.	Mania	80, strong	uncured . 120, weak
2. O.	Melancholia	100, full	uncured . 96, full
3. R.	Mania	110, weak	cured . 100, weak
4. E.	Melancholia	120	uncured . 88, weak
5. C.	Melancholia	120	cured . 88

Pulse on admission.			When discharged.	
Initials	Form of disease.	Pulse.	Result.	Pulse.
6. G.	Melancholia	80	cured	100
7. P.	Mania	100, weak	cured	100, strong
8. W.	Melancholia	120	cured	112
9. B.	Mania	100, weak	cured	100, weak
10. H.	Melancholia	120, weak	cured	100, weak
11. W.	Melancholia	64, weak	cured	88
12. M.	Melancholia	120, very weak	cured	100, of good strength
13. P.	Acute Dementia	180	uncured	114
14. S.	Mania	100	uncured	76
15. M.	Mania	100, very weak	cured	52, of good strength
16. R.	Mania	100, weak	cured	100, weak
17. M.	Mania	100, weak	uncured	84
18. C.	Melancholia	90, very weak	cured	80, much stronger
19. P.	Mania	84	cured	80
20. S.	Melancholia	80, very weak.	cured	128, weak
21. H.	Melancholia	120, weak	cured	88, weak
22. F.	Melancholia	100	cured	140
23. L.	Mania	84	cured	84
24. H.	Monomania	96	cured	96
25. S.	Melancholia	108, very weak	cured	112, very weak

The most superficial glance at the above insanity the pulse is accelerated; it was, in figures will serve to show, that in cases of fact,—

On admission.		On discharge.
from 40 to 50		in 1 case.
In 5 cases	from 60 to 70	in 2 cases.
	from 70 to 80	in 1 case.
In 6 cases	from 80 to 90	in 21 cases.
In 4 cases	from 90 to 100	in 3 cases.
In 34 cases	from 100 to 120	in 20 cases.
In 1 case	above 120	in 2 cases.

The pulse was slower than on admission when the patient left the hospital in 31 cases, quicker in 12 cases, equal in 7 cases.

M. Foville's table very nearly corresponds with the above. In 62 cases, indiscriminately selected from men and women,

In 5 cases	the pulse was, in the minute, from 60 to 70.
In 18 "	" " " " from 70 to 80.
In 23 "	" " " " from 80 to 90.
In 6 "	" " " " from 90 to 100.
In 10 "	" " " " from 100 to 120.

Disease of the heart is not uncommon in cases of insanity, but I have not met with it so frequently as M. Foville; he says that at least five-sixths of the patients at his hospital had diseased heart. Hypertrophy is more frequently found than disease of the valves; and this is what we should be led to expect, when we take into consideration the obstacles to the circulation which the heart has to surmount in mental diseases. In recent cases throbbing of the carotid and temporal arteries is frequently observed, and this should draw our attention to the quantity of blood circulating in the body, for undue pulsation of these arteries is not found only in hyperæmia, but it is observed when animals are bled to death. In considering the state of the blood and of the blood-vessels in insanity, we have been too apt, I think, to attribute everything to inflammation, without considering how many different states of the capillary vessels that term im-

plies. We have also overlooked almost entirely that the same functional disturbances are produced not only in the brain, but in other organs, by a minus quantity as well as by a plus quantity. That a state of anæmia can be produced in the vessels of the brain by depletion has been proved by Dr. G. Burrows, in the Lumleian Lectures delivered this year at the College of Physicians. It very seldom happens that we find in insanity acute inflammation — what would serve to distinguish the disease from phrenitis, if symptoms of acute inflammation were present: if there were fever, great intolerance of light and of sound, contracted pupil, and hard pulse. The ancients, and indeed the moderns, have, in their definitions of insanity, always referred to the absence of fever. It is nevertheless sometimes present, and this will guide you in your diagnosis. The fever precedes the delirium in phrenitis, but follows it in mania.

In delirium the mind is occupied solely with the past, in madness with the past and present also. In phrenitis the blood presents the buffy coat, in mania it does so very seldom. In the early part of the present century it was the fashion to bleed insane patients every spring and fall, as it was called, a custom by the way long practised in the veterinary art. Crowther, on one of these occasions, bled 150 patients at a time: the blood in every case, without exception, was free from inflamed appearance.

Dr. Haslam also says, that in more than 200 patients, male and female, who were bled, in six only was the blood sizy.

In post-mortem examinations of the insane we meet with the results of congestion and chronic inflammation, but seldom or ever those of acute inflammation. This is a subject highly deserving of your attention in a practical point of view; for if you are called in to see a patient in a paroxysm of mania, and have read that the disease owes its origin to inflammation, you would be doing very wrong if you were to bleed him freely. I believe that every variety of congestion exists in insanity, whether active, passive, or mechanical. The blood is either in excess, or deficient in quantity, and the circulating fluid acts sometimes as a poison to the brain. The reason why we find variations, I had almost said contradictions, in the mode of treating the same case of insanity, is, because one thinks only of inflammation, and bleeds, another considers the symptoms due to irritation, and employs opiates or stimulants. The same differences long prevailed with regard to the treatment of diseases of the eye, which bear a striking analogy to those of the brain: we have now pretty sure signs to guide us in applying soothing lotions to the eye, or stimulating collyria. In the treatment of a hidden organ like the brain we can never hope to be guided as infallibly; still, I trust that at some future day we shall know more fully how much to attribute to undue susceptibility, how much to passive turgescence, or how much to active congestion.

Few, I think, will be inclined to deny that there is active congestion of the capillary vessels in some cases of insanity, particularly in those of recent mania, attended with paroxysms of furor. The full pulse, the throbbing of the carotids and temporal arteries, the ferretty eye, the burning forehead, and the cold extremities, are all proofs of local plethora. But the opposite state, anæmia, has not been sufficiently considered; indeed, many, from a close resemblance of some of the symptoms, would be inclined to deny its existence, yet we know that vertigo is produced by the latter as well as by the former; and sometimes the only way we have of distinguishing the one from the other

is by making the patient stoop, and then judging whether the symptoms are aggravated or not by the gravitation of the fluid: this means of diagnosis I frequently find occasion to employ in insanity, and it serves as a useful guide in the employment of remedies.

I attended a young gentleman in 1840, who, shortly before his illness, had received several severe blows upon his face when boxing, and had lost much blood from the nose in consequence: there were also other causes which produced a drain upon the constitution, and great prostration of strength. When the first excitement of the mania had passed off, and the symptoms had somewhat abated, upon one occasion when I visited him I found the pulse reduced from 100, as it was in the first instance to 64: he was lying on a sofa, and talked to me for about ten minutes rationally: he got up to get a book which was lying on the table, and the mere change from the horizontal position brought back the delusions: he became confused and giddy, and said that he was Robert the Bruce. I have seen two cases of insanity, in one of which the disease followed a copious blood-letting; in the other it came on after frequently repeated small bleedings and violent purging. Sir B. Brodie, in a clinical lecture delivered at St. George's Hospital, Feb. 19, 1839, mentioned the case of a gentleman whom he attended who had been thrown from a high phæton, and injured his head; symptoms soon occurred which rendered venesection necessary; at the end of a week, however, he became maniacal: his ravings were like those of delirium traumaticum. One of the medical men with whom he acted recommended the blood-letting to be repeated; to this Sir Benjamin reluctantly consented. The blood drawn had scarcely any colouring matter: it hardly stained the linen on which it dropped. The mania became infinitely worse, and wine was then ordered to be administered, upon which plan of treatment he gradually became quite well.

I need hardly call your attention to the importance of this case as shewing the necessity of drawing a correct diagnosis between the delirium from an injury to the head, and maniacal furor, and the opposite manner in which mania, with anæmia and delirium, are treated. I do not, of course, mean that tonics and stimulants are to be given in every case of insanity with poverty of blood, for in this very state of the circulating fluid local plethora is frequent, and it will be necessary to subdue it before recourse is had to tonics and stimulants; I have seen much harm done by a too speedy application of these remedies. Prostration of strength, with poverty of blood, is very commonly present when the acute stage of

mania has subsided. Patients are then in a very similar condition to those in the convalescing stage of fever, and the same remedies are found beneficial in both. Passive congestions, when the blood appears to stagnate in the capillaries, not unfrequently occurs in cases of insanity.

Patients in this condition are generally weak and sluggish in their movements; little animal heat is evolved; the skin loses much of its sensibility; the pulse is so weak as scarcely to be felt. Mechanical congestion frequently accompanies this form of congestion; the extremities become livid, and effusion takes place into the cellular membrane. If you press upon the capillaries, and empty them of their contents, they are sluggishly refilled. We find also in post-mortem examinations proofs of mechanical congestion. The sinuses are found loaded with blood, and the large veins flowing into them are often very turgid. This species of congestion is also well marked during life; and it is not surprising that it should occur, considering the impediments in this disease which prevent the free return of blood to the heart. You will sometimes observe venous blood circulating in the small arteries. The lips of the patient are often blue; and if you make him bend downwards, and thus increase the impetus with which the blood is sent to the head, the lips immediately resume their natural colour. I have a gentleman under my care at the present time who labours under mechanical obstruction to the circulation, which is shewn only in the winter. There are other variations in the symptoms during hot and cold weather. In the summer he is very lively, takes a great deal of exercise, talks incessantly and incoherently; his pulse is generally between 80 and 84, of good strength; the skin is of a proper temperature, and its colour natural; his appetite is good, and he gets up of his own accord and dresses himself. In the winter all is changed; he frequently has attacks of catalepsy; he is torpid; if he walks it is in a circle; he never speaks; his pulse was 100 and very weak, the thermometer being 26° Fah.; his hands become livid; his appetite fails; he is unconscious of the calls of nature, and the attendant has great difficulty in inducing him to get out of bed.

Cold weather is always prejudicial in head affections. The statistical tables of London, Paris, Holland, and Turin, shew that cerebral congestions are most frequent in winter; and this corresponds with Dr. Heberden's opinion. We shall not therefore be surprised at finding that a severe winter increases the symptoms of those suffering under general paralysis. It is an interesting fact connected with this circumstance, that those who have been long exposed to

severe cold have a thickness of speech, and stagger as if they were drunk. M. Larrey informs us that many of the soldiers who died in their retreat from Moscow were seized with dizziness and vertigo, to which a state of somnolence and profound coma succeeded.

The insane are liable to sudden attacks of congestion, which frequently end in apoplexy. These attacks, however, are not invariably followed by disturbance either of sensation or motion. A woman who was admitted into the hospital on the 14th May, 1841, and who was labouring under puerperal mania, was on the 16th of August following seized with one of these attacks of congestion, accompanied with nausea and vomiting. She complained previously of pain in the right side of her head, and she told me that she was conscious during the whole of the time that the fit lasted, and that she felt numbness of the left side. The symptoms very soon abated, and she went out cured on the 30th August of the same year. A man, æt. 57, fell down in a fit, Oct. 22, 1841: he remained insensible only for five minutes. This case also did well. It is, nevertheless, always an alarming symptom, and one never to be treated lightly.

Congestion of the liver, not uncommon in cases of insanity, is another cause of mechanical obstruction to the circulation; the vena portæ becomes loaded, and dropsy sometimes follows: it is, however, rare, as we shall see afterwards, to meet with organic disease of this organ.

There is no symptom so common in the early period of insanity as sleeplessness. Dr. Bright attributes the frequent attacks which epileptics have in the night to alight congestion, which he says always accompanies sleep. This is the reason that the insane so often do not enjoy this temporary release from care. Unless there be some bodily disease, as fever, present, a patient should never be allowed to remain in bed during the day, as the recumbent position will of course favour the congestion.

There remains for us to consider the quality of the blood in cases of mental alienation: so intimate is the connection between the capillaries and the ultimate filaments of the nerves, both at the periphery and at the centre, that what affects the one is likely ere long to affect the other. Not only do we perceive this in the blush of shame and the paleness of anger, and in the effect which the passions have upon the action of the heart, but we see also that injury to the nerves produces stagnation in the capillary tubes, thereby of course greatly interfering with nutrition and secretion. The division of the par vagum, we learn from the experiments of Dr. Reid, is followed by disturb-

ance of the latter, arising from paralysis of the nerves of the stomach, and not, as stated by Dr. W. Philip, from want of secretion of the gastric juice, such secretion being in nowise impeded. It is not material whether the alteration in the quality of the blood is the cause or consequence of the disease. The alteration of the blood is the cause of the disease when it is deprived of the qualities necessary for supplying proper nourishment to the brain, and also when, owing to the skin, the uterus, the liver, or the kidney, not performing their proper functions, it is not properly elaborated. On the other hand the alteration is the consequence of the disease; for though nutrition and secretion are not dependent upon the nerves, yet they are materially influenced by them; and in this and other disorders of the nervous system the circulating fluid must undoubtedly suffer.

Familiar instances of the influence of poisoned blood upon the brain are to be found in the effects of alcohol and opium. No less striking are the consequences which follow when the elements of the blood are not repaired by proper nutrition. "In the progress of starvation," says Liebig, "it is not only the fat which disappears, but also, by degrees, all such solids as are capable of being dissolved. In the wasted bodies of those who have suffered starvation, the muscles are shrunk, and unnaturally soft, and have lost their contractility; all those parts of the body which were capable of entering into the state of motion have served to protect the remainder of the frame from the destructive influence of the atmosphere. Towards the end, the particles of the brain begin to undergo the process of oxidation, and delirium, mania, and death, close the scene; that is to say, all resistance to the oxidising power of the atmospheric oxygen ceases, and the chemical process of eremacausis, or decay, commences, in which every part of the body, the bones excepted, enters into combination with oxygen." Chemical analysis has not aided us at present in detecting any characteristic peculiarity in the brains of the insane. The brain of man is chiefly composed of albumen, a large proportion of water, and a peculiar fatty matter. The latter presents us with results of most interest: it was in this that phosphorus was detected by M. Vauquelin. M. Couerbe, following up these experiments, thought he could appreciate distinct variations in the quantity of phosphorus in the brains of the sane and insane. In the former he asserts that it is present to the amount of from 2 to $2\frac{1}{2}$ per cent.; in the brains of violent maniacs to that of 3, 4, and $4\frac{1}{2}$ per cent.; while in those of idiots he says that it is *deficient in quantity, being not more than from 1 to $1\frac{1}{2}$ per cent.* The value of these

experiments has been rigorously tested by M. Frémy, in a very interesting paper published in the 3d series of the *Annales de Chimie et de Physique*. "All my efforts," says he, "have been employed in studying the fatty matter which can be obtained by digesting the brain in alcohol or ether. It was after evaporation with ether that M. Couerbe discovered cholesterine, the white substance containing phosphorus, which he calls *cérébrote*, and moreover three fatty substances which he considers neutral, and which he calls *céphalote*, *stearoconote*, and *éléencephole*; (see *Annales de Chimie*, tom. lvi. p. 164.) The results which I have obtained differ in every point from those just quoted, for I have not seen in the substances of M. Couerbe anything but an acid fatty agglomeration in combination with a saponaceous compound. Setting aside the fatty substances which are found common to other animal matter, we find that the brain is characterized by the presence of cholesterine, and by two peculiar fatty acids. This composition is much more simple than M. Couerbe has been inclined to admit. M. Frémy goes on to state that, in fresh brains, the oleophosphoric acid is found, but that it soon becomes decomposed, and in a brain which has not been examined for some days you find phosphoric acid in a free state, and oleine." M. Vauquelin found the same alteration in ramollissement of the brain, which he considers to be exactly analogous to what takes place in putrefaction. It is interesting in connection with this subject to know that M. Chevreul has found in the blood the fatty matter of the brain, and M. Boudet cholesterine. M. Vauquelin has, also, in some cases, found the peculiar fatty matter of the brain in the liver, which is certainly a discovery of much importance: it may, perhaps, throw some light upon the subject of sympathy between the brain and the liver. We must rest contented for the present with the theory of sympathy to explain the mutual action and reaction of the central organs of the nervous system with each other, and with the nerves themselves. Esquirol lays much stress upon this subject, and draws our attention to the connection existing between the ganglia of organic life and the brain, as leading us to trace the source of the disease to the ganglia. The central parts of the nervous system do, as we know, sympathize with the functional and organic disturbance of all organs of the body. The opinion, therefore, that insanity is sometimes a sympathetic disease, is not so very improbable as some have supposed; but, whether sympathetic or idiopathic, it becomes a matter of great importance in practice to consider the diseases with which insanity may be complicated, and to relieve the symptoms not only which take their

origin from the disease of the brain, but those also which are due to the disease existing at the same time in any other organ, as the mental disease will undoubtedly be much aggravated if attention is not paid to the latter. As there is no disease in the body with which insanity may not become involved, so there is no medicine in the Pharmacopœia which you may not have at some time or other to prescribe in treating mental affections. The search after specifics for the cure of madness does, therefore, appear to me to be as vain as the labours of the alchymist to discover the philosopher's stone. Although there is no disease with which insanity may not be complicated, yet there are some more commonly met with, in conjunction with it, than others; *e. g.* scrofula, phthisis, inflammation of the lungs, disease of the heart, congestion of the liver, diseased kidneys, inflammation of the mucous lining membrane of the intestines, diarrhoea, erysipelas, epilepsy, apoplexy. Sometimes an attack of diarrhoea, of phthisis, or of fever, will put a stop to the attack of insanity; sometimes the attack will be merely suspended. The approach of the catamenia is always a critical period with our female patients; the disease is then often aggravated, and paroxysms of furor occur; the return of the monthly period sometimes gives an intermitting character to the disorder, and the hopes of the friends and of the physician are alternately raised and depressed. It is not uncommon to meet with insanity manifesting itself in one member of a family, while nervous disorders akin to it develope themselves in the rest. This takes place, also, occasionally, with respect to other diseases, which are not of a nervous type, *e. g.* scrofula and phthisis. A patient under my care, who died of general paralysis, was the only one of ten children who did not die of phthisis.

[To be continued.]

ON A NEW TEST FOR CORROSIVE SUBLIMATE.

To the Editor of the Medical Gazette.

SIR,

ALLOW me, through the columns of your journal, to call the attention of those interested in the science of toxicology to a method of detecting corrosive sublimate, which I am not aware to have been previously brought before the public.

It is now upwards of two years since, reflecting on the strong affinity of metallic silver both for metallic mercury

and for chlorine, I triturated a grain of corrosive sublimate with several grains of pure metallic silver in powder, as it is procured by precipitation with copper from a solution of the nitrate, and in a dry state; and I was soon encouraged by the blackened appearance of the mixture to believe that decomposition of the bichloride had taken place in some degree at least; and that this decomposition was complete became evident when, upon placing the powder in the bulb of a small tube (such as is used in reducing arsenic), I obtained a distinct ring of metallic mercurial globules in the neck of the tube. Since that time, in obtaining metallic mercury from corrosive sublimate, I have always used silver, which I have not known to fail in producing its reduction, and have found much more convenient and manageable than the potassa fusa, commonly employed; this last not being easily pulverised, and attracting moisture to an inconvenient extent very rapidly. This objection, however, scarcely applies to the use of the bicarbonate of soda or potass.

I have subsequently endeavoured to ascertain whether metallic silver possessed the same power, and to what extent, over corrosive sublimate in solution; and in successive trials I have been able to obtain distinct, nay abundant, metallic globules from the amalgam formed by boiling metallic silver in a solution containing one grain of corrosive sublimate in four ounces of distilled water, and even in a solution of half that strength, *i. e.* of one grain to eight ounces. My time does not allow me to make numerous comparative experiments, but I am disposed to believe that silver acts slowly, or not at all, on solutions of corrosive sublimate at the ordinary temperature.

I next tried this method of experimenting on organic mixtures; and having added one grain of corrosive sublimate to four ounces of tea, made with sugar and milk, I boiled the liquor with the powdered silver, and after allowing time for subsidence, the fluid was poured off. Liquor potassæ was boiled for some time upon the metal, to dissolve organic matter, and liquor ammoniæ afterwards added to the sediment, in order to dissolve the chloride of silver. This was also poured off, and the sediment having been washed and

thoroughly dried, was placed in a tube as before, and metallic mercury obtained in abundance.

Two other experiments have also given very satisfactory results, in one of which one grain of corrosive sublimate, dissolved in a little distilled water, was mixed with a gelatinous fluid, made by diffusing 3j. by weight of the patent gelatine of the shops in 4 oz. of New River water. In the other, one grain of the same substance in powder was added to 5 oz. of a sanguineous fluid, which had been obtained five days previously, by tapping, from the head of a hydrocephalous infant. The only modification in these cases was, that the mixture was acidulated with hydrochloric acid before adding the silver; this proceeding having been suggested by M. Reinsch's plan of testing for arsenic. It is necessary to moisten the silver by agitating it with a little distilled water in a tube, before adding to the suspected mixture; but, in the cases detailed, the metallic sediment has been very easily obtained, subsiding rapidly, and the results have been very satisfactory.

No actual case of poisoning has occurred to me since I have tried this method, and my professional engagements leave me little time for pursuing the investigation of its powers; but I submit it your readers not without a hope that in other and more skilful hands it may be productive of important results.

I have the honour to be, sir,

Your obedient servant,

ALGERNON FRAMPTON, M.D.

Assistant Physician to, and Lecturer on Toxicology at, the London Hospital.

29, New Broad Street,

ON THE PRODUCTION OF UREA AND URIC ACID.

To the Editor of the Medical Gazette.

SIR,

IN Dr. Golding Bird's "remarks" published in your journal of May 12th, I have been misinterpreted on the subject of Liebig's doctrines. I shall feel obliged by your insertion of this note of explanation.

Dr. Bird appears to understand that, in my observations upon a recent review, I attempt to explain the fact of a diminished proportion of uric acid having occurred in certain cases of chlorosis by

810.—XXXII.

the existence in that affection of a decided deficiency of blood-corpuscles. This is an error. On turning to my paper in the *Lancet* of April 15th, it will be found that I refer the fact to a diminished nutrition and change of matter in the tissues, and a more perfect oxygenation of the effete particles than would happen if the usual quantity of matter had been changed in the vital process. At the same time, I admitted that the reasoning is hypothetical, and that the case furnishes an apparent exception to Liebig's views. Dr. Bird employs his own misrepresentation of my statement for the purpose of rendering one part of the subject inconsistent with another part.

Dr. Bird leads his readers to the inference that I "denounced" the statement, that 107 grains of organic matter are daily excreted by the skin, as most fallacious. This, again, is an error. I admitted the fact, being fully aware of the source from which it was derived. The writer of the review in question resorted to it for the purpose of showing that the function of the skin is of great importance in the removal of azotised compounds from the body, and I stated my belief that the fact was thus employed most fallaciously. Until it be proved that urea is a general, and not merely an occasional constituent of the cutaneous secretions, or, as respects the particular animal substance which the skin is said to secrete, until a description is given, more accurate than a vague resemblance to an undefined compound and, in particular, until the amount of azote which that substance contains is determined, I am likely to remain of the same opinion. Allowing for the nitrogen contained in the cast-off epithelium scales, I am aware of nothing which justifies the conclusion that the elimination of azotised compounds by the skin is an important part of its function.

For the purpose of invalidating Liebig's theory of the uric acid of the urine being one step in that series of metamorphoses by which the azotised compounds cast off by the living structures become more and more highly oxidised, until they finally disperse in the atmosphere in the forms of carbonic acid gas and ammonia, Dr. Golding Bird asserts that he has advanced a fact. Birds, we are informed, void a large quantity of uric acid, which

ought not to be the case. The Doctor complains that I have omitted to notice this objection of his to the Professor's theory.

I do not think we have as yet sufficient data to enable us with accuracy to apply the principles of Liebig's physiology to all classes of animals. This is the case with some graminivorous animals, and still less do we know of the carnivorous birds, on which the objection is founded. Among the few facts published regarding the metamorphoses occurring in the latter, there is one which Berzelius states on the authority of Coindet. "The urine of carnivorous birds contains *urea*, but it is wanting in the urine of those birds which live on vegetable food, notwithstanding this consists of acid urate of ammonia." This fact is derived from a foreign source; perhaps, therefore, Dr. Bird regards it as one which should be deemed valueless. The above objection as well as others advanced by Dr. Bird, is founded on a partial application of Liebig's theories to states of life in which some only of the data are as yet known.

With regard to the state of the iron in the blood, I believe Dr. Kane has not as yet given us any facts. If Dr. Bird will draw a different conclusion from the experiments of Gmelin and Liebig than they themselves—if he will also come to a different conclusion as to whether Dumas is to be considered more trustworthy than Mulder, Liebig, and Scherer, in analysing fibrin—and Dr. Kemp is equal in analysis, and as good an authority on the bile, as Berzelius—I hope we shall be allowed the exercise of our judgment in receiving those conclusions.

Dr. Bird, finally, misinterprets me with regard to personality towards himself or others in my observations. My object is only to forward the truth, and not even to reply to those personalities in which Dr. Bird indulges. I feel, accordingly, that I am precluded from entering further than is necessary with him into these deeply interesting topics.

I am, sir,

Your obedient servant,

HENRY ANCELL.

ON PSEUDO-ERUCTATION.

By G. C. CHILD, M.D.

Physician to the Westminster General Dispensary.

(For the London Medical Gazette.)

It is well known that there is no more frequent attendant upon hysteria than flatulence. This is easily accounted for by the fact, that hysterical affections are usually associated with more or less of indigestion and irregularity in the evacuation of the bowels. In many cases, however, the production of air in the intestines is so enormous and so sudden that dyspepsia of the ordinary kind has been deemed inadequate to account for it, and it has accordingly been attributed to a special effect of the hysteria upon the secreting vessels of the intestinal mucous membrane.

No sign of hysteria is better known than this excessive flatulence. The abdomen sometimes becomes tympanic even during the short period of the patient's examination: the eructation is loud, well-marked, and distressing. Anti-flatulent medicines are indicated, and produce the best effects.

But there are hysterical disorders, common enough in practice, where the flatulence is only *apparent*, and belongs to the class of mimoses. This fact is, I have no doubt, familiar to those who have seen much of the disease; but I infer that it is perhaps not so generally known as it ought to be, because I have had patients under my charge whose most troublesome symptom was, as they imagined, flatulence, for which they had been perseveringly treated with stimulants and carminatives, but of course without the least benefit.

I never saw this species of mimosis displayed better than in a patient who is at present under my care. This woman, about the middle period of life, is a pew-opener, exceedingly nervous and hysterical. During the last seven or eight years she has received a good deal of medical advice for headache, indigestion, palpitation, and pains in the abdomen; for the last of these complaints she has been frequently bled and cupped, and, I fear, too actively treated. At present she complains of fluttering at the heart, faintness, with occasional sharp pains, and anomalous sensations in various parts of the body. One of the symptoms from which, she says, her greatest suffering proceeds is

"wind." According to her account she sometimes belches up enormous quantities of it for hours together. The abdomen is swollen, and resonant on percussion.

In the course of treatment I have had several opportunities of observing these "attacks of wind," and what I am now about to remark is gathered from this and from similar cases.

When the face of a person affected with this pseudo-flatulence is watched steadily for a minute or two, a characteristic expression may be observed, although it is difficult to describe it; I shall only say that it is quite different from that of a person who is actually bringing up wind. The face is kept averted from the practitioner, and the quantity of air which passes out seems very little when compared with the efforts made for its expulsion. It will be remarked that the mouth is kept shut, so that the air passes from the nose only, and sometimes the mouth is held firmly by the hand, or even the nostrils are partially closed by it. This act has of course a tendency to impede rather than to favour the exit of the air: but the reason for it will immediately appear.

As in the paroxysms of hysterical cough or convulsions, so also in this complaint, there is much irregular and tumultuous action about the upper part of the throat, the muscles of the tongue, pharynx, and the levators and depressors of the larynx, being chiefly involved. A loud rumbling or forcible movement of air may be perceived in the same situation, but there is seldom any distinct flatulent "rapport." Under the heart, and over the abdomen generally, there is no movement of flatus to be detected; occasionally there is a short quick contraction of the diaphragm, as in hiccup.

The fit can be instantly stopped by simply causing the patient to keep her mouth open. This is the diagnostic mark between true and pseudo-flatulence. It is obvious that keeping the mouth open cannot impede the passage of air from the stomach, but it deprives the patient of the power to emit those sounds which simulate eructation. To produce these sounds the mouth must be shut and the posterior nares closed. The various muscles of deglutition are then thrown into *strong and irregular action*, and

by this means the compressed air is forcibly made to circulate about the different parts of the mouth and pharynx. During these efforts air is often pressed into the gullet, whence it either returns into the mouth again, or is swallowed into the stomach. Of this fact I am very sure, that in many cases of hysterical flatulence there is more air swallowed into the stomach than expelled from it.

If any one will try to imitate the act above described, he will, I think, be able to produce sounds more or less resembling eructation. I know some who can mimic it perfectly, but on causing them to open their mouth the air is no longer enclosed in a shut cavity, and the power to produce the pseudo-eructation is lost. In making the trial one will generally be conscious of swallowing air involuntarily.

In a patient who fancied that her complaint was a "windy dropsy," it was found that pressing or rubbing the arms or legs immediately brought on a paroxysm of this pseudo-flatulence. I could not help remarking how similar this case was to those mentioned by Morgagni (*De Sed. et Causis Morb. Epist. 43*): the first reflects credit on the practical tact of Santorini:—

"I was at Venice when a woman sent for surgeons and physicians, and among them Santorini, in order to ascertain the nature of the tumor, which was prominent in one of her groins, as she feared lest it should be a bubonocoele; for this reason, that it appeared suddenly, as she was straining to discharge the hardened excrements from the intestines. All signs of a hernia were absent, except that immediately upon applying their hands to that part, the woman discharged wind by eructation. Santorini, observing the physicians to be in doubt merely on this account, smiled, and said to them, 'Whatever part of my body you touch, you will have eructations come on.' They instantly made the experiments, and found it to be as he had said. When Santorini related these things to me, and to some more friends, others wondered at it as an unheard of circumstance; but I (Morgagni) said it is extraordinary indeed, yet not unheard of. In Bartholin you will really find the observation of a man 'who from a slight friction of any part of the body, immediately fell into so enormous an

eructation, that he did not cease to eructate before the friction ceased*."

The above sentence, marked with inverted commas, applied exactly to the woman with "windy dropsy," to whom I have alluded. I have no doubt they were all examples of pseudo-eructation. On reading the quotation just made, I am inclined to suspect that Santorini knew the trick, and was quizzing his brother practitioners: but it does not appear that Morgagni was aware that it was simply a deception, otherwise his surprise and wonderment would scarcely have been so great.

MEDICAL GAZETTE.

Friday, June 9, 1843.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.

We publish this day a notice of the annual dinner of the "Society for Relief of Widows and Orphans of Medical Men in London and its Vicinity." This inconveniently long name it seems has been borne by the institution ever since the year 1788, and is somewhat remarkable in these days of rapid movement, and of successful search after ease and material comfort. It reads almost as laboriously as the titles of some old books, where the author appears hardly to have been restrained from putting the whole table of contents into his title-page.

This peculiarity, by the way, though generally abandoned, is still found in some controversial tracts, and seems to be a natural result of people earnestly putting forth what they have to say, and being more anxious for the success of their cause than for the elegance of

their style. Towards the close of a controversy, when zeal has cooled, when the less informed, but not less earnest, have made room for the stronger or more skilful disputants, those in whose hands the contest is left shew more skill in their weapons and more judgment in their selection, knowing how much depends on their length, their weight, their balance. "See that my staves be sound and not too heavy," is one of the Duke of Gloster's commands on the eve of Bosworth Field. "Last night it more fatigued my arm than foes," is the Corsair's complaint of his scimitar.

Homer makes a burly hero do much execution with a huge stone; but this great poet,—or to avoid controversy this "able editor" of all the hero-poetry of his day,—the blind Ionian ballad-singer,—would never have put such a weapon into the hands of Achilles or of Ulysses. Long, awkward, and laborious names, then, are apt to be faithful exponents of real facts, while shorter and more concise ones are often mere theories and professions of things which ought to be, but are not.

The title, however, of this society has at least this virtue, that it does not mislead the reader, but faithfully sets forth its purpose, and an inspection of the annual statement of its affairs will convince those who take the trouble to inquire that it is doing, with no small success, what it professes.

This society seems to have been originally a club formed by certain London practitioners of eminence for the purpose of making a fund the proceeds of which should be divided amongst the widows and children of members, or rather amongst such of them as should be left in a state of indigence.

From the high professional standing of the first founders, it is evident that their intentions were principally benevolent, and that their contributions

* Translation of Morgagni by Dr. Alexander, 1769.

were destined for the families of their less opulent neighbours, rather than for their own; but the encouragement held out soon induced many to subscribe from motives of prudence, and the gradual increase in the proportion of those whose families became claimants for relief proved the expediency of contributing to the fund, and brought into full relief its value as a provision against the contingencies of early death and inadequate savings.

The union of provident and benevolent objects which this society accomplishes, while it is calculated to attract two very different classes of subscribers, must nevertheless tend also to deter many of each class; and the very small number of members, which has never exceeded 350, is a sufficient proof that many of each class fear that their own personal objects may not be the most effectually attained by its means. Unlike an insurance office, the investment in this fund can never be profitable, except in case of a degree of destitution which few are willing to believe will be the probable lot of their own families, and many defer the securing an income for their surviving dependents until they can afford to provide one which shall do more than place them above the reach of want. By some, indeed, who have contributed largely to the support of this institution as the best hitherto formed, strong objections are entertained to the principle on which it acts. They consider it as a temptation to neglect adequate and liberal provision for a family, and to be content with a state but one remove above pauperism, which may be dangerous to industry and burdensome to society. But it is urged on the other hand that life insurance even to a moderate amount is very expensive, even if commenced early in life, and if long deferred often becomes impossible. It is difficult,

too, to believe that those who in early life have, by joining a society like this, insured their families against absolute privation, will be on that account less likely, with the increase of their ability, to make further provision by ordinary modes of insurance.

It is also contended that this society is deficient in not having a purely benevolent fund, the benefits of which might be extended beyond the families of its own members. Such an addition would be very desirable, but as many of the subscriptions are obtained from members who ought not in common prudence to indulge largely in the luxury of alms-giving, it is perhaps more desirable that a separate institution should be formed which should accomplish this object, and the contributions to which should be left more to the discretion of the benevolent according to their respective means.

Another very forcible objection to this society is, that those who do require its assistance are obliged to solicit that assistance, as a favour, which they should have a claim to as a right: many men dislike their families being exposed to this humiliation: but if the original object of the society, and the mutual good will which suggested and sustains it, be duly kept in view, and if proper kindness and delicacy be preserved in the manner of affording relief, this objection will lose all its force.

When trades and crafts first emerging from mere feudal vassalage protected themselves by corporate alliances, the admission of each member into a trading company was subjected to certain restrictions. These kept the numbers of those who were admitted within convenient bounds, and gave to each, when once admitted, a sort of family interest in the whole body of which he became a member; the trades of each town even had their respec-

tive powers of excluding from the local exercise of their calling all who had not contributed by servitude or compensatory payments, or both ; in return for which the member obtained a claim for protection in his calling, and for support in old age and destitution. But as monopolies and exclusive privileges became obnoxious, and were gradually diminished or abolished, the protection which they afforded was withdrawn at the same time, and their place has been gradually supplied by voluntary associations for the relief of the decayed and the destitute, for the widow and the orphan ; so that, at the present time, there is hardly a trade or a profession which has not a fund raised for these purposes. But it is obviously much easier to keep up by stringent regulations the levy of customs or dues on entering a profession, than to awaken and keep in action that prudence and forethought in individuals which are required to supply their place, when those customs are disused, and perhaps the efforts of clear-sighted and earnest philanthropists cannot be more beneficially exerted than in pressing home on the indolent and the indifferent the urgent necessity that exists for individual forethought and self-denial. Compassion and alms-giving will never cease to be estimable, but the more extensively the need for them can be diminished, by a sound and healthy self-dependence, the better for a nation and for society. The parliamentary evidence elicited by the contemplated Poor-law for Ireland shows how grievous are the effects of shameless mendicancy and reckless almsgiving, though the one be called contentment, and the other charity. Perhaps at no time did members of the medical profession stand more in need of mutual support and co-operation *than at the present.* The claims of

our art to public estimation are trenched upon by quackery ; the most obvious truths and established axioms denied by those who have neither sufficient information for argument nor docility for belief ; and the advantages of our recent discoveries are neutralized by undue contempt of former theories : the honest refusal to assert for itself that infallibility which is impudently claimed by quackery, all concur to diminish the aggregate of our gains, while the numbers who are to share these gains are far beyond what can be supported—all these things concur to render the preservation of individual and general independence more than ever difficult. Yet on this independence must we rely for the power of sustaining our present difficulties, and of amending our future condition.

The constitution of this society appears to be purely democratic ; the members elect by ballot their own officers, and surrender the entire management of affairs into their hands, the acts of the Court of Directors being finally subject to the veto of the General Court. The ordinary Courts of Directors are held four times a year : perhaps, considering the amount of business to be done, and how desirable it is to keep up a spirit of activity in promoting the accession of new members, this is too seldom. The General Courts are held half yearly.

The Medical Benevolent Society was established in the year 1816, and is intended for assisting such of its members as may, by illness, or other causes, be incapable of supporting themselves. It has a wider range of operation, but, though established 27 years ago, contains but 150 members, yet it has afforded much very effectual and seasonable relief, and has received the gratitude and the pecuniary support of some who had accepted its assistance. The constitution and government are almost

exactly similar to those of the "Widows and Orphans' " Society, to which most of its members are also contributors.

Public dinners, and public advertisements, are no doubt highly useful for promoting harmony and good feeling amongst the members of a society, and can hardly be dispensed with in this country, but the speeches which follow are not calculated to promote a deliberate consideration of its claims to support, nor do public advertisements appeal with sufficient distinctness to individuals. Surely a statement of the nature, objects, and efficiency of these two most laudable institutions should be addressed to every member of the profession, and the deliberate opinion of each should be taken as to the propriety of giving them his support. The corporate bodies especially should be appealed to, that each member of the profession might have the subject pressed upon his attention immediately on admission. These bodies might take a useful hint from the Medical Association, which has established a fund for the relief of destitution, the benefits not being confined to its own members. We cordially agree with the wish expressed by Dr. Wilson, "that the Councils of this Society" (for the Relief of Widows and Orphans of Medical Men, &c.) "instead of being held at a coffee-house in Holborn, should transact their business in the hall of a Royal College; and that its limits should be extended till they included every member of the profession in the United Kingdom, or even in the British possessions." The Army and Navy have each a fund for medical officers; it is, we believe, obligatory on all to subscribe to it, and its operations are very much of the nature of an insurance.

Perhaps not one of our readers has escaped an appeal for relief from a medical man, or his family, in complete destitution: such appeals he has been

unwilling either to reject or to encourage on insufficient grounds: he may have given without hope of conferring real benefit, or refused without feeling justified in withholding. Joining a society such as we have described, he may, by his recommendation and his example, encourage sound prudence, and confer effectual relief.

THE DINNER.

THE annual dinner of the society above alluded to took place last Saturday, at the Freemasons' Tavern, Great Queen Street, and was attended by about 70 of the members and their friends. H. R. H. the Duke of Cambridge presided. *Non nobis Domine* having been sung, and the usual loyal and patriotic toasts given, his Royal Highness called attention to the objects of the society, which were to provide a fund for relief of the families of deceased members, who might have failed in struggling against the difficulties of their profession, or been worn out in its practice, and died without having realized a sufficient maintenance for their surviving relatives. His Royal Highness felt assured that such an institution was exceedingly necessary, from the very great difficulties with which medical men had to struggle, and the casualties to which they were liable; and he was most happy to find how much this society had done to relieve those who had been obliged to make claims on its funds. His Royal Highness read part of the annual statement laid upon the table, from which it appeared that the society had relieved, within the past year, 31 widows and 20 children, distributing for that purpose nearly £1300, in half-yearly payments; and that £385 had been added to the capital stock, which now amounted to nearly £41,000.

His Royal Highness expressed a hope that the society would not only continue to afford the same amount of relief, but to increase it when necessary, and that many would prove by their contributions that evening that they felt, as he himself did, warmly interested in its prosperity. His Royal Highness subsequently added, on his own health being proposed, that it gave him great pleasure to express thus publicly his best wishes towards the society; and that as it had been intimated that he could serve its interests by becoming the Patron, he had much pleasure in accepting that office, and hoped that he should at all times be found able and willing to promote the society's welfare. This gracious announcement was of course received with hearty cheering.

Mr. Bacot, the acting treasurer, announced that the investment of the capital with the Commissioners for the Reduction of the National Debt had already produced a considerable increase in the half-yearly income, and stated the present condition of the society to be certainly flourishing; but that it must be borne in mind, that according to calculations made long ago, and which had hitherto proved correct, the number of claimants, though actually smaller this year than the last, would *increase for the next twenty years*. To meet this demand, therefore, and to secure permanent efficiency and stability, would require the most careful management on the part of the directors, and the utmost exertions of friends and supporters. The recent investment with the Commissioners was owing, he said, to the suggestions of three members, viz. Dr. Mann Burrows, Mr. Dover, and Mr. Maclure.

The usual toasts were given in succession, and duly responded to; and we are happy to add that 308*l.* 15*s.* were collected on the occasion.

FELLOWES' CLINICAL PRIZE REPORTS.

BY ALFRED J. TAPSON.

University College Hospital, 1842.

[Continued from p. 217.]

CASE XI.—*Melancholia coming on during pregnancy, without much, if any, derangement of the general health; considerably relieved by aperients, morphia, and tonics.*

ANNE HUNTER, æt. 31, admitted July 6, 1842, under Dr. A. T. Thomson. A woman of rather slender conformation; melancholic temperament; dark complexion; naturally rather florid, but now sallow; black hair, &c. Is married, and had four children, two of which only are living, and the younger is only five weeks old. Her father died some years since: about two years before his death he was deranged for four months, owing to disappointment in business and loss of property; he however recovered from this perfectly, and died sane, but was hemiplegic. No other member of her father's family was ever deranged. Her mother is living, and well; she has two cousins on her mother's side now in lunatic asylums.

She has been a map-colourer ever since she was quite a child, and has had consequently much confinement, and sometimes works as many as eighteen hours in the twenty-four. Her health has always been good, and habits regular. She used to be very nervous about ten years ago, but this *she got the better of*.

The present attack, she states, came on

about six months since, when she got into a very violent passion with another woman, without any definite cause, and since then she has always felt distracted, never having a moment's peace of mind, and constantly so much discomposed, that she has been able to do nothing, neither to read nor think, nor follow her employment; is worse sometimes than at others, but not at any particular times, nor worse in one posture than another, but generally a little better towards evening.

It is not easy to describe correctly the state of her mind: she does not brood over any particular point or event, but feels a great desire to die, so great indeed that she says she would destroy herself if she had the means in her power; her feelings are so horrible that she says she cannot live; she seems to be persuaded that she is destined to eternal misery, do what she may; she says it is only running against providence to think differently: as a proof of her lost condition, she declares that she now hates her elder child, whereas she used to love him very much.

This state of mind came on quite suddenly, without any other apparent cause than that already mentioned; she was on good terms with her husband, never had any fits, &c.: she thinks her recent confinement had very little effect on her mind in any way, and thus disappointed her, as she had hoped to have got well then.

From the commencement the most prominent symptom had been sleeplessness, and this caused her to apply to a surgeon soon after it began. He gave her some "sleeping powders," and ever since she has been obliged to take opium, in order to obtain any sleep, though before the present attack she used to sleep very well. She has been in the habit of taking enough hard opium to make a good-sized pill every night, and sometimes another during the day, but never more. The effect of each dose she has always found to be to cause her skin to tingle and perspire, and to render her more composed and tranquil; her mouth and throat are dry in the morning, and indigestion and constipation have been produced, rendering aperients necessary. Her appetite does not appear to have been impaired, but it was never very good. Also, since she has taken the opium, her complexion and skin in general has become very yellow, and this was never the case before, except when she had a bilious attack, to which she was rather subject, and this temporary derangement of the secreting function of the liver was always increased by the opium. She has also got thinner and weaker. Latterly the opium seems to have lost its specific quieting effect, and her only hope of obtaining rest being thus annihilated, she was reduced to despair.

July 8th.—The surface of the body gene-

rally is warm and comfortable, except the feet, which, she says, are always cold, even after taking the opium; the complexion has a very dingy sallow tinge; the eyes are surrounded by a very dark circle; the expression of the countenance is very much depressed, and she frequently sighs deeply; the tongue is coated with a thick white fur; the appetite moderate; thirst normal; pulse 74, regular, moderately full and soft. During the two nights she has been in the hospital she has slept much better, though she has taken no opium; bowels costive; evacuations not particularly pale; urine free. The heart's sounds are natural, and the breath sounds quite healthy.

Habeat Haust. Purg. Statim.

9th.—The bowels have been freely opened.

℞ Morphine Acetatis, gr. ij.; Mice Panis, gr. xij. M. f. pil. viij. Sumatur una quinquè quâque horâ.

℞ Tinct. Gent. Comp. f3j.; Infusi Gentianæ, f3xj. M. f. haustus. Inter sing. dos. pilul. sumendus.

11th.—Slept very well last night, except being much alarmed by a dream; did not feel so oppressed when she awoke this morning as she commonly does, and now feels much less irritable, and is in better spirits, and looks considerably more cheerful; pulse 84, tolerably full and firm; pupils natural.

12th.—Talks with more freedom about herself, and now, though still very indifferent about living, yet she seems to have no desire to destroy herself. Dr. Thomson recommended her some active employment.

14th.—Improving steadily; sleeps soundly all through the night, without dreaming, also sleeps in the day-time after taking the morphia; expression of countenance much more animated; eyes brighter; pupils natural; no headache; says she will live now if she can; appetite increased, though it has never been very bad; bowels keep regular without the aid of medicine.

16th.—Has unpleasant feelings at times, but not very frequently; the tongue has a milky villous appearance on the surface, but there is a purplish tinge beneath this, and some of the papillæ are enlarged.

Adde Haust. Quinæ Disulph. gr. j.; et Acidi Sulph. Dil. ℥viiij.

20th.—Continues to improve; complexion becoming clearer, and is less dark round the eyes; the feet are never cold now as they used to be, indeed they generally feel quite warm; she feels that she is gaining strength, and is active and cheerful; the head feels clear, and she can command her thoughts sufficiently to read a little at a time. The morphia produces just the same effects as it did at first, she sleeps as long after each dose, and the skin tingles a good deal after it.

23d.—Does not seem to have made much progress during the last few days, but on the whole she is very much better than she was.

26th.—She was allowed to leave the hospital yesterday for an hour, but did not return till this afternoon, and says she feels much worse for not having slept last night.

28th.—Improved again considerably; slept well; spirits improved; appetite much better than it has been for a long time.

August 1st.—Discharged at her own request.

REMARKS.—In the preceding history we have a description of the state of mind in a well-marked case of melancholia; or if it were desirable to give it another name, it might almost be termed "suicidal monomania," her leading desire being to die, either by her own hand, or by some other means.

The reasoning faculties of her mind did not appear to be much, if at all, perverted, except when she thought of her destination, as she believed, to eternal misery. She seemed to fancy that she was possessed of some evil spirit, over which no being, either human or divine, could exercise any authority. Even on this point, however, she was able in a limited degree to reason correctly; for after stating that her only wish was to die, and that had she the means of death in her power she would use them instantly, she added, "It's a dreadful thing to hurry into eternal misery, which I know I must do if I destroy myself."

Thus it was evident that her mind was much perverted on this subject. No motive urged seemed to have sufficient influence to rouse her to voluntary and cheerful exertion: so great was the mental dejection, that all hope seemed to be extinguished, and a settled despondency held undisputed possession of her mind; so that whilst to outward appearance the mind seemed to be in a state of tranquillity, "it was," as Dr. Prichard remarks, "a deceitful calm, concealing profound grief and misery."

Almost the only bodily symptom accompanying this state of mind was sleeplessness; and this may reasonably be attributed to the state of the mind: indeed, all her organs seemed to be perfectly healthy. This freedom from bodily disease forms one of the means of diagnosis from hypochondriasis, in which disease there are almost always dyspeptic symptoms, on which the patient continually dwells, and which he delights to magnify. It was also distinguished from this by the suicidal disposition that was evinced; for in hypochondriasis, notwith-

standing that they fancy they shall soon die, they take extremely good care not to injure themselves. Again, in this latter disease there is a disposition to dwell with tedious minuteness on all their sufferings, real and imaginary; whereas here there was a marked disinclination to talk at all: all the patient's desires might be summed up in that one word—rest. We shall say nothing more respecting the diagnosis, as it was so well marked, and there is no other disease besides hypochondriasis with which there is any chance of confounding melancholia; and by attending to the preceding points there can be no difficulty in that respect. The patient, when brought into the hospital, was said to be labouring under puerperal mania; but besides wanting the characters of that, it had existed long before delivery, and that process, we have already stated, had no marked influence on the mind either one way or the other.

Several causes probably co-operated in producing it. As predisposing causes we may mention, 1st, that her father was deranged, though not till many years after the patient's birth; and in his case the madness appears to have been produced by disappointment in business; also the patient had two cousins on her mother's side in lunatic asylums at the time of her admission: therefore we may fairly assume that there was an hereditary predisposition to some form of mental derangement. 2d. Her temperament was decidedly melancholic; and this is stated by Dr. Prichard to be a very powerful predisposing cause to melancholic madness. 3d. Her employment was sedentary in the extreme, and had often been very severe: this would, of course, tend to weaken the body, and thus to unnerve the mind. 4th. Her age was that at which this species of mania usually shews itself.

The only exciting cause appears to have been of a moral nature; at least she attributed the attack to her getting into a very violent passion about six months before her admission: from that time she has never felt as she did before. At the same time, she scarcely seems to believe that this could have been a sufficient cause, for she said that had she done anything very bad she should not have thought so much about it; but she knows no other cause. The attack was not preceded by pain any where, nor fits of any kind. No symptoms of disease of the brain or of any other organ.

In noticing the treatment, we shall first consider that which had been used previous to her admission into the hospital. It is stated that she had been in the habit of taking an opium pill once, and sometimes *twice a day, almost ever since the commencement of the attack; it used to compose her mind, but was beginning to lose its*

effects. As a natural consequence of this habit, her digestion became deranged, her bowels were costive and aperient medicines necessary, and her complexion became sallow. The last is a well-known consequence of a habit of taking opium; and here there seemed to be a particular reason why it should do so, for it appears that she had been subject to bilious attacks, at which times her skin used to become yellow, and opium would be sure to increase it by diminishing the secretion of bile.

At the time of her admission, the principal indications of treatment were—1st, to quiet the nervous system, and to procure sleep; 2d, to attend to the secretions generally, especially of the bowels and liver; and 3d, to give tone to the system in general, so that it might not be necessary to continue indefinitely the use of the means for fulfilling the first indication. The treatment was commenced with a purgative draught, to open the bowels freely; and this was ordered to be repeated afterwards as often as it might be necessary. To fulfil the first indication she was ordered a quarter of a grain of morphia every five hours; and to fulfil the third, a draught containing gentian, &c.

The effects of this treatment were soon apparent. We find that in two days she slept well, but was alarmed by dreams, and very soon slept soundly without dreaming; and her desire for dying left her, and that natural desire for the prolongation of life returned. Her appetite increased, and with it her strength and spirits; and her complexion became clearer. Her improvement was gradual and steady, except at the time when she remained out of the hospital for a night: she soon recovered this, and was not long after discharged at her own request.

MEDICAL REFORM.

To the Editor of the Medical Gazette.

SIR,

THE subject of medical reform having received fresh interest from the great probability that something definite is soon to be brought forward in parliament, I request a small space in your journal for a few remarks upon a subject connected with that question; and knowing how valuable that space is, I will endeavour to be as brief as possible.

Without therefore entering into the point of the necessity for this reformation, I shall at once take it for granted that the measure is to be carried; but at the same time I shall conclude that even if the general practitioner is to be in future a bachelor of medicine*, his position with the public, and the public

* Vide Sir James Clark on Medical Reform.

demand for the general practitioner will remain much in the same state as at present ; that is, there will always be, 1st the consulting practitioner or physician ; 2d, the general practitioner, or the practitioner who sends his own medicine and gives a lengthened credit, and there will be also the prescribing chemist, who sells at a cheaper rate behind the counter. The public must have the family attendant ; that attendant must supply all medicines and give a lengthened credit ; in other words he must be in one respect in exactly the same position as the tradesman. This has been the case from time immemorial, and as long as the public demand exists there will always exist a sufficient number of medical men to supply that demand. It is on the preliminary education of the medical practitioner, be he called what he may in the forthcoming measure, that I wish to make a remark. This education has heretofore commenced by a term of apprenticeship, and I think I am justified in declaring that there exists a decided feeling throughout the profession against the system ; but I wish to invite a calm consideration of this old-established institution before it is too late, before reform shall have swept it away as useless and unnecessary. I admit that its utility has much diminished, and that in too many instances it has been made a vehicle for oppression, and its duties converted into drudgery. It was instituted when the medicine of the apothecary was an art and mystery, and consisted in pure empiricism ; it took its origin before lectures were generally delivered in London ; and therefore a period of eight years in the apothecaries' shop was well spent, and was the only means of obtaining medical knowledge. The student's channel for the prosecution of medicine in the country is not only diverted, but his duties have, from the more perfect division of labour throughout the profession, been confined to one monotonous duty, that of dispensing. This office, too, in many instances has precluded the possibility of reading, which is now essential, and these idle habits have been engendered at a most important period of life. These are some of the evils, it must be allowed, which have too often acted prejudicially, not only to the student himself, but have done much to disgrace the whole system of apprenticeship. The evil appears to be, that while every other part of the profession has advanced, this useful institution has remained all but stationary ; or, if it has altered at all, it has become more monotonous and tedious.

I would first show in what I consider its usefulness chiefly to consist, and therefore that it should be preserved, in at least a modified form, in any future measure affecting medical education.

I have concluded, I think justly, that the demand for the practitioner practising pharmacy, or rather sending his own medicines, will continue of necessity, allowing that all scientific knowledge is now obtained at the hospital and medical schools. I maintain that there is much essential though not scientific knowledge which cannot be taught there, nor in any other place than in the surgery of the general practitioner ; the species of knowledge to which I allude is not easily described, but consists in an infinity of small matters relating to the proper management of the surgery, the method of book-keeping generally adopted, the proper economy of time, including all the more commercial part, down to the proper receiving and attending messages at the door. But this is not all ; a student can obtain but a very limited knowledge of the materia medica, the cost of drugs, the best mode of buying them, preserving them, and their state of purity, by merely attending lectures on the subject, and examining the specimens in rotation. It is by having them constantly before him, weighing them, dividing and subdividing them, that a more thorough and intimate knowledge can be obtained of them. I will allow that physicians obtain a knowledge of materia medica without this dispensing, but the general practitioner has something more to attend to.

He has to purchase them, and is himself always responsible for the quality ; he ought therefore to know more than merely their medical properties.

I would here state, however, that though I think that the total abolition of apprenticeship would be inexpedient, I would allow that the period of it might be shortened to three years ; and it must be allowed that the above duties, to be obtained in the surgery only, and which require but very little mental exertion, might be taught in much less time than three years, and that three years' exclusive attention to them would be great waste of time ; yet they require a lengthened practice rather than any close application.

But there is another reason for the continuance of medical apprenticeship, and that is, the youth, at the age at which he enters on his medical studies, requires to be properly overlooked, which he could not be at any hospital or collegiate establishment in London, or in the provinces ; for even in Oxford and Cambridge, where the whole town is under the authority of the Universities, there is difficulty in exercising proper control over the student. How could this, then, be done in the heart of London, or in any other large city ?

I conceive, therefore, that there is a necessity that the youth entering the profession should be placed under the eye and surveillance of a medical practitioner ; for if

PRESSURE.

I consider the following are only
as for the proper instruction of medi-
cal apprentices; and if six apprentices could
be received at the same time, they could be
taught; though to one or two pupils they
would be impossible. In the first place,
nearly every drug, and every preparation in
the London Pharmacopœia, should be kept
in the surgery, and, as far as possible,
should be prescribed occasionally. A proper
laboratory for the preparation of the chemi-
cals, and for the pursuit of practical che-
mistry, should be established, and it should
be furnished with all necessary philosophical
apparatus for elementary instruction in
chemistry and general physics. An her-
barium, illustrating at least all the natural
and artificial orders of plants; the skeleton,
and a good collection of separate boxes for
the study of osteology; a library, consist-
ing of anatomical botanical plates, and most of
the elementary works on medicine. I con-
sider that with six or eight pupils, and the
usual rate of remuneration given to clergy-
men who take pupils, that is, at least £100
to £120 per annum, all the above advan-
tages could be given—a sum, by the way,
which is frequently denied to the medical
man, but which is freely given to the lawyer,
clergyman, architect, engineer, or farmer.
The depreciation, however, is as much, it is
feared, to be attributed to the profession,
because they have consented to take less,
than to the public. The outlay would be at
first considerable, but it would never have
to be repeated, and the pleasure and gratifi-
cation of having efficient apparatus and
ample opportunities for scientific pursuits,
and inducements for keeping pace with every
discovery and improvement of the day,
which is often next to impossible with the
routine of a private practitioner, would fully
compensate many for the first expense.

As I have too far trespassed on your space,
I will reserve what I had to say on the man-
ner in which this plan could be developed,
and at present subscribe myself

Your obedient servant,
W. H. O. SANKEY.

Margate, May 29, 1843.

ANEURISM CURED BY PRESSURE.

*Case of Popliteal Aneurism cured by Com-
pression of the Femoral Artery.* By ED-
WARD HUTTON, M.D. Surgeon to the
Richmond Hospital.

MICHAEL DUNCAN, æt. 30, a labourer of
rather healthy appearance, but of intemperate
habits, was admitted into the Richmond
Hospital on the 3d of October, 1842. He
stated, that ten days previously, while suffer-
ing from cramp in the right leg, to which
he had been subject for the last year, he, for

[illegible]

Xps 18.—The printer found the
 letter to contain the following: "The
 to the Government of the United States
 and I understand from one of your men
 being inferior to the others that the
 Mr. Yaff and another is a member of
 of which is known to the Government.
 Having no more to say, I am
 for the improvement of your men
 after inspection of the letter, I am
 it is fine case. I will be
 subject of pressure being made by a man
 paid upon the surface of the letter, and
 and the counter-pressure upon the opposite
 surface of the letter without interfering with
 the collector's circulation."

In the first instance the compression was made upon the frontal lobe of the middle third of the skull and although it was effective in compressing the tumor it produced so much edema that it could not be sustained, and after a few applications the apparatus was removed and adjusted to the upper part of the head.

12th.—The femoral artery was compressed as it passes from the pelvis under Poupart's ligament, and the pressure maintained for more than four hours.

14th.—The tumor feels rather more solid; the purring thrill, before felt on the re-entrance of the blood into the sac, is no longer sensible; the pulsation as before.

18th.—No change in the tumor.

19th.—The circumference of the limb at the seat of the tumor is a quarter of an inch less than at the last measurement.

From the above information, it is noted that the above information is not sufficient to determine the exact date of the above information.

On the 21st of December the tower was
reached in the early morning and
the first night was the one of the
most severe.

It was found that the machine was not working. The reason was that the wire was not properly connected. It had been in the wrong position.

STROKES.—SAY the case reported by Cheadle has treated with success by similar means a case of popliteal aneurism in Dr. Stevens' Hospital, and Dr. Bellingham another in St. Vincent's Hospital. It would appear that this plan of treatment has been too hastily abandoned by the profession, probably from the compression employed being so excessive as to render it quite insupportable to the patient. The least possible pressure which may be sufficient to close the vessel should be used, and when this cannot be sustained, it will prove of use to partially compress the artery, so as to lessen the impulse of the stimulation. In cases where the aneurism is small, this treatment would be successful before resources should be exhausted.

We are happy to be able to add Mr. Cusack's case.

Case of Popliteal Aneurism cured by Pressure. By Mr. CUSACK.

JOHN LYNCH, æt. 55, a tanner, of short stout build, admitted into Stevens' Hospital, No. 4 Ward, January 17, 1843, under Mr. Cusack. Last autumn he had a bad fever, from which he recovered slowly; about five weeks since he began to experience burning pains running from the knee down to the ankle, particularly along the outer and anterior part of the leg; these continued until seven days before admission, when, as he was walking in the street, he suddenly felt a very acute pain in the ham, running to the ankle, and compelling him to sit down; he put his hand to the part, and, for the first time, felt a lump there the size of his fist; he got home with some difficulty, but the pain gradually decreased, and next day he went about his business as usual; during the following days the lump became much smaller, so that, on admission, it was not more than half its original size.

He has been in the habit of carrying heavy burdens up a ladder; has had cough and palpitation of the heart since the fever; used to drink freely, but has lived temperately for the last twenty years; never used mercury.

On examination, there is a tumor in the lower angle of the left ham in the course of the popliteal artery, about the size of a hen's egg; it is elastic, and pulsates synchronously with, but more powerfully than, the heart; the pulsations are as evident laterally as on the superficial surface; moderate pressure on the femoral artery stops them, and empties the tumor, so that it can scarcely be felt; the skin is not discoloured, nor is the tumor tender on pressure, except at a point on each side the size of the top of the finger; it is smooth and even on the surface, and a distinct bruit can be heard when the ear is applied to it; the anterior and posterior tibial arteries cannot be felt in either feet; what vessels can be felt appear to be large, and to have thin coats; no morbid sound can be detected in the heart, but its impulse is weak, and the pulsations very intermittent and irregular; the pulse at present is 70, small and irregular, but it varies from 60 to 90, without any apparent cause; the left lung is emphysematous; the superficial veins of his cheeks are much enlarged, giving a dusky red appearance; temperature of both limbs the same.

22d.—A roller was applied lightly from the toes up to the groin.

Habeat tinct. Digitalis gtts. v. ter in die.

Feb. 4th.—No apparent difference; if the bandage is not very carefully applied, it gives him severe pain in the instep after ten or

twelve hours; to-day a compress was laid over the tumor, and the bandage put on as before.

Tinct. Digitalis gtts. x. ter in die.

22d.—No change in the tumor. Mr. Hutton came to-day and applied his instrument; the pad being screwed down on the femoral artery at as high a point as possible, and with a force sufficient to stop completely the pulsations in the tumor; a compress was then laid over the aneurism, and secured by a flannel bandage, beginning at the toes: he soon began to feel uneasy, but when it had been on for one hour and a half, his face became pale, his pulse weak and slow, and he complained of faintness, with a feeling of weight in the situation of the pad, running up to his heart, and the sensation of a rush of blood to the head, accompanied by profuse perspiration on the forehead and vertex; the instrument was now loosened, and he soon rallied; when quite recovered, the pad was again screwed down, but he could not bear it for more than half an hour at a time.

Cont. tinct. Digitalis gtts. x. t. d.

24th.—He bears the instrument as long as he can, and then loosens it, screwing it down as soon as he is free from pain; he complains most of the rush to his head; the pad slips off the artery very easily; he says he can tell by a peculiar sensation of something running up from the situation of the pad, when the pulsations in the tumor are stopped, but he often gives an erroneous opinion; to-day the instrument was put on loosely, so as only to lessen the force of the pulsations.

Cont. tinct. Digitalis gtts. x. t. d.

27th.—He has been very patient and quiet, but no effect has been produced on the aneurism. Mr. Hutton's instrument was left off, and a bandage applied. Temperature of both legs the same throughout.

Cont. tinct. Digitalis gtts. x. t. d.

March 4th.—Same as at last report.

Tinct. Digitalis gtts. xv. ter die.

16th.—Sir P. Crampton's instrument, modified by Mr. Daly, was put on, so as merely to lessen the impulse in the aneurism; no compress or bandage was put on the tumor. Pulse 63, very intermittent: it soon rose to 90.

Cont. tinct. Digitalis, gtts. xv. ter die.

18th.—He bears this instrument much better than the other; has none of that unpleasant rush to the head; complains chiefly of soreness produced by the pressure of the pad; this is relieved by dusting the part with flour. No change in the tumor.

Omitte tinct. Digitalis.

22d.—The tumor is decidedly harder and smaller, the impulse being greatly lessened ; at times there is only a thrill in the aneurism ; sometimes there is no motion whatever in the tumor, even when the pressure is removed, but it returns on the slightest movement of the body ; he observes that the two spots before mentioned have lost all tenderness on pressure. Complaints of cough. Pulse 67, very irregular.

Mist. expect. c. tinct. opii camph.

23d.—Pulsation has totally ceased ; the tumor is very hard, and about the size of a large walnut ; a large artery can be felt running down superficially to the aneurism, over which it can be easily rolled with the finger ; it then divides into two branches : the articular vessels do not appear to be enlarged.

On the 19th he had some oedema of the leg, for which a bandage was put on the limb ; for the last two nights he has had a most intolerable itching in the thigh, but there is no redness or mark of any kind.

25th.—Instrument was removed to-day. The femoral artery can be distinctly traced as far as the opening in the tendons of the triceps and vastus int.

Mist. expect. c. Aq. lauro cerasi.

April 1st.—The tumor is decreasing ; the enlarged artery above mentioned is much smaller than at last report ; the relative temperature of the limbs, as ascertained by thermometer, has not varied.

7th.—Tumor continues to decrease ; the entire artery can be traced until it enters the aneurism, but in the lower third of the thigh and in the ham the pulsation is so weak that it can only be felt on a careful examination.

Cont. Mist. expect.

April 14th.—Tumor can now be grasped with facility ; the enlarged artery has become very small, while the popliteal of the affected limb now pulsates as strongly as that of the sound one ; a number of hard cords can be felt passing over the tumor. The palpitations of the heart still continue. Pulse 68, intermittent.—*Dub. Journ. of Med. Science.*

ON THE REMOVAL OF CALCULI FROM THE BLADDER OF THE HORSE.

BY MR. MOGFORD, V. S.

My attention has been arrested by an article in your number for January on lithotomy ; a few observations on which, as they are the result of my own experience, will not, I am sure, give offence to that justly respected operator, Mr. Field. I cannot forbear from again expressing my surprise that, in opera-

tions of this kind, veterinary surgeons do not make use of the means so peculiar accessible to them, viz. inverting the bladder through the rectum. Mr. Percivall has very kindly noticed my mode of operation in the third volume of his Lectures and the second of his Pathology.

I first extracted a stone from the bladder in this way in the year 1820, and the case was published by Mr. White in 1824. No operation could be more simple or less exposed to dangerous consequences. There was no inflammatory symptom whatever, and the horse was soon after hunted. In fact, all that is required is a scapula and a probe-pointed bistoury, for the arteries are easily avoided without any guide.

In proof of my assertion I may state that I have more than once introduced a stone into the bladder, and extracted it in the same way.

About two years ago I introduced, by way of experiment, an egg into the bladder of a mare, and extracted it again, whilst she was in a standing position. As this was done in a private manner, I thought it advisable to have witnesses. I, therefore, introduced the egg into the bladder again, and left it there until the following morning, when I found that the bladder was full to bursting, as the mare was afraid to stale.

At my request, three medical gentlemen of this island kindly accompanied me the next morning to witness the operation ; but being puzzled by the fulness of the bladder, and having no catheter at hand, I introduced, as a substitute, the nose of a bellows, which answered the purpose pretty well, although the large quantity of water in the bladder retarded the operation. Notwithstanding this, however, the operation was performed within a minute, and without breaking the egg, although the shell had been considerably softened by the action of the acid of the urine. In order to put the whole matter beyond a doubt to the spectators, I again introduced the egg. The mare was then killed, the bladder taken out, and shewn to them with the egg in it.

There is some degree of tact required in the operation, the want of which has probably, on many occasions, prevented its adoption. When the arm is first introduced into the rectum, the animal forces against it, in order to expel it ; the arm must remain quiet, until these struggles have ceased, when the operator may proceed without difficulty. If the finger should not be sufficiently long to reach the neck of the bladder from the opening, the latter may be pushed towards the finger from the rectum.—*Veterinarian.*

HEMIPLEGIA FROM TYING THE
COMMON CAROTID ARTERY.

M. SEDILLOT applied a ligature to the common carotid to arrest hæmorrhage, in a man who was wounded behind the right branch of the lower jaw. Complete hemiplegia of the left side of the body, and of the right side of the face, followed, and the patient lost his intelligence so far that he could scarcely comprehend questions put to him. He died nine days after the application of the ligature, and the post-mortem examination showed that the hemiplegic symptoms had resulted from the right side of the brain having been deprived of its due proportion of arterial blood.—*Gazette Médicale*; and *American Journal of the Medical Sciences*.

A TABLE OF MORTALITY FOR THE
METROPOLIS,

Shewing the number of deaths from all causes registered in the week ending Saturday, May 27, 1843.

Small Pox	10
Measles	34
Scarlatina	27
Hooping Cough	85
Croup	5
Thrush	2
Diarrhœa	3
Dysentery	1
Cholera	2
Influenza	0
Ague	0
Typhus	59
Erysipelas	4
Syphilis	1
Hydrophobia	0
Diseases of the Brain, Nerves, and Senses ..	129
Diseases of the Lungs and other Organs of Respiration	256
Diseases of the Heart and Blood-vessels	23
Diseases of the Stomach, Liver, and other Organs of Digestion	68
Diseases of the Kidneys, &c.....	7
Childbed	9
Ovarian Dropsy	0
Disease of Uterus, &c.	3
Rheumatism	0
Diseases of Joints, &c.	8
Carbuncle	0
Ulcer	0
Fistula	0
Diseases of Skin, &c.....	0
Diseases of Uncertain Seat	88
Old Age or Natural Decay.....	65
Deaths by Violence, Privation, or Intemperance	17
Causes not specified	3
Deaths from all Causes	859

NOTICE.

We regret that we cannot give insertion to the paper of Mr. T.

WILSON & OOLVY, 57, Skinner Street, London.

THE LONDON MEDICAL GAZETTE,

WEEKLY JOURNAL
OF

Medicine and the Collateral Sciences.

FRIDAY, JUNE 16, 1843.

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE XXX.

*On the causes, symptoms, and treatment of
preternatural labours.*

IN preternatural labours, which form the third class of Smellie and Denman, the head of the child does not present as in natural labours, but the nates and inferior extremities, or one of the shoulders and arms. Cases of prolapsus of the umbilical cord, and twins, may be included in the same class. It is very difficult, or impossible, to explain why the head of the child does not invariably present in labour, or assign a cause for the same women having preternatural presentations in several successive labours, the head of the child being rarely if ever in them the presenting part. Violence inflicted on the mother during pregnancy will not explain their occurrence once or oftener in the same individuals, for they take place where there has been no shock sustained during gestation, and they are seldom met with after the most severe accidents experienced during pregnancy. That they are not the result of accident is proved by the fact that in some women the same shoulder and superior extremity has presented in different labours, and the children have certainly been placed transversely in the uterus before the commencement of labour.

On July 31st, 1836, I attended a lady in labour, in whom the left superior extremity of the child presented, and the operation of turning was required: I was informed that in both her previous labours

the left superior extremity had presented at the beginning of the labour; the situation of the child was the same, and it was alive in all the three labours at the commencement; yet she had been exposed to no shock or accident of any kind during pregnancy. Another patient had eight preternatural labours in succession. The arm presented in the first four or five, and the nates and inferior extremities in all the others. A woman was delivered twice at the British Lying-in Hospital in three years, and in both labours the right shoulder and arm presented. In a woman with distorted pelvis the inferior extremities presented in the first and third labours, and an arm in the fourth. Another, who has been delivered five times, had presentations of the nates and inferior extremities in four labours, the first only being natural. It is highly probable that some cases of preternatural presentation may arise from twisting of the umbilical cord around the neck, trunk, or extremities of the foetus. Of the sixty cases of arm presentation related in these Clinical Reports, there was prolapsus of the funis in fifteen. The death of the foetus in utero is, I believe, a more common cause of preternatural labours than twisting of the cord around the child. Of thirty cases of arm presentation related by Dr. Denman, in which spontaneous evolution took place, or the children were expelled double, only one was born alive, and the greater number were premature, and probably dead before the labour commenced. "One hundred and twenty-seven cases of presentation of the feet occurred in the Dublin Lying-in Hospital during the mastership of Dr. Collins, not including those met with in twins. Sixty-two of the 127 children were still-born; forty of which were *putrid*. Thirty-six of the 127 were premature, viz. four at the fifth month; seven at the eighth month; twenty-eight of the premature children were *putrid*; four were dead, but not *putrid*, and four were born living."

Mauriceau states that when the foetus is dead the labour is almost always protracted and difficult, and the reason he assigns for this is probably correct: "*à cause que son corps n'ayant plus de soutien, et étant devenu tout mollassé, ses parties s'affoissent tout en un tas les unes sur les autres : ce qui fait qu'il vient aussi pour l'ordinaire en mauvaise situation, ou quoiqu'il se présente par la tête en figure naturelle : les douleurs de la femme sont si foibles et si lentes en cette occasion, qu'elles ne le peuvent pas faire expulsion.*" But there are other and more obscure causes of preternatural presentations than the death of the foetus and twisting of the cord around the trunk and extremities, of which we at present know as little as Dr. Denman did when he wrote the following passage in 1795. "It seems doubtful, therefore, whether we ought not to exclude accidents as the common causes of these presentations, and search for the real cause from some more intricate circumstance; such as the manner after which the ovum may pass out of the ovarium into the uterus; some peculiarity in the form of the cavity of the uterus or abdomen; in the quantity of the waters of the ovum at some certain time of pregnancy; or, perhaps, in the insertion of the funis into the abdomen of the child, which is not in all cases confined to one precise part, but admits of considerable variety."

Women often suspect during the latter months of pregnancy that the child is not in the natural position, and that when labour comes on it will be a cross birth, when their fears are unfounded. But they are not always mistaken, for some who have before had natural labours have been firmly persuaded, from something unusual in the form of the abdomen, that the child was unfavourably situated, and their suspicions have been confirmed by the result of the labour. In the greater number, however, it is only after the labour has commenced and made some progress that we ascertain that some other part than the head presents. In preternatural presentations, particularly when the extremities present, the membranes are either ruptured at the commencement of labour or soon after, or they have a peculiar conical pointed shape, not the ordinary globular form, and protrude far into the vagina. Sometimes, before the os uteri is much dilated, the membranes, filled with liquor amnii, pass into the upper part of the vagina, and form a considerable sac with a narrow neck. The presenting part either cannot be felt, or it is lighter, and when touched gives less resistance, than the head usually does, and is less smooth, hard, and regular. A hand, or a foot, or the umbilical cord, may sometimes be distinctly felt *through the membranes*, but more frequently

the membranes burst as soon as the dilatation of the os uteri commences, and the first thing we touch on making an examination is an extremity in the vagina, or perhaps protruding through the external parts. The spontaneous and premature rupture of the membranes, or something peculiar in their shape—the presenting part lying so high up within the os uteri, after it is considerably dilated, that it cannot be felt by an ordinary examination—the presenting part, if felt, being more moveable, less smooth, and globular, and resisting, than the head, are the chief circumstances which should induce you to suspect that the presentation is preternatural, and make you, by all means in your power, preserve the membranes entire, and prevent the escape of the liquor amnii until the uterus is so much dilated, or is so dilatable, that the operation of turning, if necessary, may be performed. As soon as we are certain that the head does not present, it is right to state the fact to the nurse, if not to the relatives of the patient.

Before the membranes are ruptured, it is difficult in some cases to determine positively whether the head presents, or the nates; and it is not unusual for those who have been some years in practice, and who are not afraid of committing mistakes, to make a hasty examination, and to believe and state that it is a natural labour, but afterwards discover, to their mortification, that the nates present. If you touch one of the nates through the membranes, you will feel that it is round, like the head, but much softer, and that there is no suture nor margin of the parietal bones to be felt, however carefully you endeavour to make out the presentation. After the most careful investigation, if you remain in doubt about the nature of the case, whether the head presents or the nates—if you are certain that it is not the shoulder—there is no ground for anxiety; the only circumstances requiring attention are, that the membranes should not be ruptured artificially, and that you should not state to the nurse and patient that all is going on favourably before you are positively certain of the fact. After the membranes give way, you will readily ascertain that the nates present by the cleft between the buttocks, the anus and external parts of generation, and the escape of the meconium. The shoulder is much more pointed than one of the nates, and if you can pass the finger carefully around all the parts within your reach, where a shoulder presents you will not fail to distinguish it by feeling the ribs and the scapula. The parietes of the thorax communicate a peculiar sensation which you cannot fail to recognise. The hand is much flatter and broader than the foot, the fingers are much longer than the toes, and they differ from one

another in length much more than the toes do, and are more separated from each other; their extremities are uneven. The middle finger is the longest and the thumb the shortest part, and it is at a distance from the fingers. The foot is thicker and heavier than the hand, the great toe is the most prominent part, and near to the other toes; the toes are shorter than the fingers, their ends form nearly an even line, descending from the great toe. But the heel projects in a remarkable manner, and it is by feeling the heel that you will never fail to distinguish the foot from the hand in the uterus: you may forget all these distinctions between the fingers and toes during the operation of turning, but if you will take the trouble once to examine attentively the heel of a new-born child, you will never bring down an arm

into the vagina instead of a leg, as I have seen done.

Treatment of presentations of the nates and inferior extremities.

If the nates present to the centre of the brim of the pelvis, the abdomen of the child may correspond with the spine or abdomen of the mother; it may be directed backward or forward, or the back of the child may be directed to either side of the mother. Some of these positions are more favourable than others; that which is most so is represented in the following figure from Smellie's plates, in which the fore-parts of the child are to the posterior part of the uterus, and the funis, with a knot upon it, surrounds the neck, arm, and body. "I have sometimes felt," he says, "in these cases, when labour

was begun, and before the breech was advanced into the pelvis, one hip at the sacrum, the other resting above the os pubis, and the private parts to one side; but before they could advance lower, the nates were

turned to the sides and wide part of the brim of the pelvis, with the private parts to the sacrum, as in this table; though sometimes to the sacrum, as in the following table. As soon as the breech advances to the lower

part of the basin, the hips again return to their former position, viz. one hip turned out below the os pubis, and the other at the back parts of the os externum.

In this case the child, if not very large, or the pelvis narrow, may be often delivered alive by the labour-pains; but if detained long at the inferior part of the pelvis, the long pressure of the funis may obstruct the circulation. In most cases, adds Smellie, where the breech presents, the effect of the labour pains ought to be waited for till at least they have fully dilated the os internum and vagina, if the same have not been stretched before with the waters and membranes. In the meantime, whilst the breech advances, the os externum may be dilated gently during every pain, to allow room for introducing a finger or two of each hand to the outside of each groin of the foetus, in order to assist the delivery when the nates are advanced to the lower part of the vagina.

But if the foetus is larger than usual, or the pelvis narrow, and, after a long time and many repeated pains, the breech is not forced down into the pelvis, the patient's strength at the same time failing, the operator must, in a gradual manner, open the parts, and, having introduced a finger into the vagina, raise or push up the breech of the foetus, and bring down the legs and thighs. If the uterus is so strongly contracted that the legs cannot be got down, the largest end of the blunt hook is to be introduced, and cautiously drawn down with it. As soon as the breech or legs are brought down, the body and head are to be delivered, as described in the next table, only there is no necessity here to alter the position of the child's body.

This figure, also from Smellie's plates, shows, as he states, in the same view as the former figure, the breech of the foetus presenting: with this difference, however, that the fore parts of the child are to the fore

part of the uterus. In this case, when the breech, coming down double as it presents, is brought down to the hams, the legs must be extracted, a cloth wrapped round them,

and the fore parts of the child turned to the back part of the woman. If a pain should in the meantime force down the body of the child, it ought to be pushed up again in

turning, as it turns easier when the belly is in the pelvis than when the breast and shoulders are engaged; and as sometimes the face and forehead are rather towards one of the groins, a quarter turn more brings these parts to the side of the pelvis and a little backwards, after which the body is to be brought down. If the child is not large the arms need not be brought down, and the head may be delivered by pressing back the shoulders and body of the child to the perineum, and whilst the chin and face are within the vagina, to bring the occiput out from below the pubes, according to Davenport's method. Or the operator may introduce a finger or two into the mouth, or on each side of the nose, and, supporting the body on the same arm, fix two fingers of the other hand over the shoulders, on each side of the child's neck; and in this manner raise the body over the pubes, and bring the face and forehead out with a semicircular turn upwards from the under part of the os externum. All this may be easily done when the woman lies on her side; but if the child is large and the pelvis narrow, it is better to turn the patient on her back, and after the legs and body are extracted as far as the shoulders, the arms are to be cautiously brought down, and the head delivered. If the woman has strong pains, and when, by the felt pulsation of the vessels of the *funiculus umbilicalis*, or the struggling motion of the foetus, it is certain that the child is still alive, wait with patience for the assistance of the labour; but, if that and the hand are insufficient, and the pulsation of the *funiculus* turns weaker, and if the child cannot be brought double, the breech must be pushed up; and if the resistance of the uterus is so great as to prevent the extraction of the legs, the patient ought to be turned on her knees and elbows. When the legs are thus brought down, the woman, if needful, is to be again turned to her back, to allow more freedom to deliver the body and head, as before described. If the head, after several trials, cannot be delivered without endangering the child, from overstraining the neck, the long curved forceps ought to be applied. If these fail, and the patient is not in danger, some time may be allowed for the effect of the labour pains; which likewise proving insufficient, the crotchet may be used, when it is certain that the child is dead, or that there is no possibility of saving it."

The treatment adopted in cases of nates presentation by Dr. Burton, a contemporary of Smellie, was still more artificial and objectionable; for as soon as he discovered that the nates presented, he was accustomed to thrust up against the buttocks with all his strength, and to endeavour to turn the child with its belly towards the os uteri,

and then search for the feet. "Were this rough and barbarous recommendation of Burton generally followed," observes Dr. Merriman, "the most lamentable consequences, both to mother and child, could not fail of being often experienced. Smellie was too fond of this pushing up; indeed it was the doctrine of the day; and Dr. Hunter, in the early part of his practice, used to follow the same plan in breech presentations; but, from a conviction of its impropriety, he afterwards discontinued it." "At this time I lost the child in almost all the breech cases," says Dr. Hunter, "but since I have left these cases to nature, I always succeed." Portal, who first described the best method of treating face presentations, was probably also the first who discovered that cases of nates presentation might often be left to the natural efforts, and that they did not require the operation of turning upon the head, or that attempts should be made to bring down the feet. "In such a case as this," he says, "you must not be impatient, for though the labour proceeds very slowly, yet it is not much more difficult than a natural birth; whence it is that our midwives say, by way of proverb, that where the buttocks can pass, the head will follow of course. The position of the child in this case is doubled, with his thighs upon the belly, and the passage being once open for the buttocks by the reiterated pains, the head follows without much trouble."

Having ascertained that the nates present, whatever the position of the foetus may be, whether the abdomen look backward or forward, we cannot alter it with safety, and no change can be required to be made till the nates and lower extremities are expelled. The os uteri dilates slowly in most cases of nates presentation, but we cannot employ any means with advantage to accelerate the delivery, and in most cases, if we do not interfere, but wait patiently, they are gradually pressed lower and lower into the pelvis, and at last escape from the vagina without any assistance. If the os uteri and vagina are imperfectly dilated, and the nates are drawn down or pass rapidly through the pelvis, the child is often lost. The membranes should not be ruptured, and the expulsion of the nates should be left entirely to the natural efforts, unless the labour is protracted and exhaustion takes place. Except supporting the perineum, nothing is required in a great proportion of these cases before the nates and lower extremities have been expelled, when it becomes necessary to ascertain precisely the relative position of the child to the pelvis, to rectify this if it is unfavourable, and artificially extract the superior extremities and head, to prevent the fatal compression of the umbilical cord. If we find, after the expulsion of the nates

and lower extremities, that the toes are directed forward, or that the child is in the position represented in the second figure, with its abdomen applied to the anterior part of the uterus, and that its back lies along the spine of the mother, we should wrap the nates and sides in a soft napkin, and turn the child very gently round during a pain, observing to which side the feet are inclined to turn, till its abdomen is to the spine of the mother, and the toes are directed backward to the hollow of the sacrum, or to the side of the pelvis. In many cases, the nates turn round in the passage spontaneously, so that it is not required artificially to alter the position. It is necessary always to recollect that it is possible to turn the body of the child round without turning the face round into the hollow of the sacrum, and that the chin may be over the symphysis pubis when the front of the chest and abdomen are turned backward. After the lower extremities and body of the child have been expelled, and placed in the most favourable position for the extraction of the superior extremities and head, it is necessary to proceed without loss of time to draw these through the pelvis, that the child may not be destroyed by compression of the umbilical cord. As pressure upon the cord for a very short time will in some cases kill the child, it is proper to watch closely the pulsations of its arteries. Draw the body of the child forward as far as the arm-pits, and place it in this manner [exhibiting it upon the phantom] over the palm of your right hand and forearm, and gently draw the body towards the left thigh of the mother; then pass the fore and middle fingers of your left hand along the back part of the left arm of the child to the elbow-joint, and press down the arm with your fingers along the thorax of the child, and extract it. Then transfer the body of the child and left arm to your left hand and forearm for support, and with the fore and middle fingers of your right hand disengage and bring down, in the same way, the right arm of the child; then pass the fore and middle fingers of your left hand into the mouth of the child, or rather over the lower and upper jaw, and at the same time place the fore and middle fingers of your right hand over the back part of the neck and occiput, and with the fingers of the two hands thus applied extract the head, in the line of the axis of the pelvis. The perineum is very rigid in some cases of nates presentation, where it is the first child, and it will be torn if the head is extracted hastily, and not drawn forward to the symphysis pubis. When you feel the pulsations of the cord beginning to cease, you may be tempted to employ greater extracting force than the neck of the child and perineum can bear, and both may be destroyed. The only me-

thod of obviating this is to press back the edge of the perineum, that the air may gain admission into the mouth of the child, and the respiration go on, when the circulation in the cord has been arrested, until the perineum is sufficiently dilated to slide back over the face, and allow the head to pass. I have seen from twenty minutes to half an hour elapse in some cases after the cord had ceased to pulsate, before the perineum would allow the head to escape, during which time the respiration was regularly performed. This is not a new practice: it has been alluded to by some of the older accoucheurs, and some others; and the advantages to be derived from it were fully pointed out some years ago by Dr. Bigelow, in a paper published in the American Journal of the Medical Sciences, "On the Means of affording Respiration to Children in Reversed Presentations." The object of Dr. Bigelow in this paper is to show that in many cases the life of the child may be saved by forming a communication between the mouth and atmosphere previous to the delivery of the head. If the head be low down, the fingers alone can give the necessary assistance; but if it is high in the pelvis, and is reached with difficulty, the assistance of a tube may be necessary. He recommends a flat tube, which is to be guarded, and kept within the fingers of the inserted hand.

Where the pelvis of the mother is small or distorted, and the child large and unfavourably situated, the efforts of nature may be insufficient to expel the child, either alive or dead. The nates may become so firmly impacted in the pelvis, that they cannot advance without artificial assistance. A finger should be passed up to one of the groins, and when a pain comes on a considerable extracting force may be exerted with it, without injuring the child; or a soft handkerchief may be passed between the thigh and abdomen, and the nates drawn down; but this cannot be done unless they have descended low into the cavity of the pelvis. Where these means fail, and it is impossible to extract the child alive, the blunt hook or crotchet must be employed. In cases of nates presentation, where the pelvis is distorted, after the extraction of the trunk and extremities, it is necessary to perforate the back part of the head, and complete the delivery with the crotchet. In presentations of the feet and knees, the treatment does not essentially differ from that required in presentations of the nates.

CLINICAL LECTURES

ON THE

THEORY & MEDICAL TREATMENT
OF INSANITY,*Delivered at St. Luke's Hospital,*

May 1st, 3d, and 5th.

BY ALEXANDER JOHN SUTHERLAND.

LECTURE II.—concluded.

Post-mortem examinations.

I HAVE now to draw your attention to the morbid appearances found after death in the brain and viscera of the thorax and abdomen. It must not be expected that the exact nature and seat of the alterations in the encephalon can be pointed out as manifesting the disease; I have never found any thing in the brain of the madman which could be said to be characteristic of his disorder; although there are very few cases which have not presented some morbid appearance either of the brain or its membranes. I think that medical men generally expect too much when they are called upon to examine the encephalon in a case of insanity. The brain is sliced to the centrum ovale, and the examination ends in disappointment. It was not thus that Foville examined the brain; every minute alteration in the cortical and medullary structure was carefully noted by him, and a healthy brain was compared with the madman's brain as often as circumstances would permit.

In laying the results of my post-mortem examinations before you, I shall commence with the scalp, and describe the morbid appearances according to the order in which the structure presents itself. The integument of the cranium is sometimes remarkably thin, and loosely attached to the parts beneath, and I have occasionally observed beneath the scalp a round circumscribed swelling containing fluid.

The shape of the cranium does not appear to have any connection either with the production or species of the disease. Many of our uncured patients have very well-formed heads; some, on the contrary, with badly-formed heads have got well. Georget says, one encounters, among madmen, the same formation of the head as among those of sound mind. Foville asserts that this is not strictly correct; there were more than 50 malformations of the cranium in the 300 patients then in the hospital. I conclude that this remark applies to the madmen only, and not to the idiots under his care. The *receding of the forehead is the most striking alteration of the bone, and therefore, perhaps,*

most frequently observed in insanity. I have seen a patient the shape of whose head corresponded exactly with the description of that of Thersites, *φοξος εην κεφαλην*. The bones of the cranium differ very much in appearance in different madmen. Sometimes they are so thin as to be translucent, at other times they are preternaturally thickened; the thickness is also sometimes unequal. In some, the diploë has entirely disappeared, and the bone is hard and brittle; in others it is more than usually developed, and the external table is comparatively soft and yielding. Rough deposits of bone and spiculæ are found in various parts of the inner surface. The eburnated cranium which is sometimes found was supposed by Gall to have been accompanied by a disposition to commit suicide: this has been proved not to be correct.

Alterations of the membranes.—As in all cases of chronic inflammation, so in insanity, the dura mater adheres firmly to the inner table; so firm has been the adhesion sometimes that I have been obliged to remove the divided membrane with the skull-cap. In one case only I have observed extravasation of blood between the bone and the dura mater. The patient died of epilepsy. The first fit came on Dec. 6th, 1838, from which day to the 10th she had about fifty (they came on in such rapid succession that it was difficult to remember the exact number); coma followed, which terminated in death on the 13th. The dura mater was found much injected; separating this membrane from the inner table was an extravasation of blood the size of a half-crown; corresponding with this was an extravasation of blood beneath the scalp. In injuries to the head I need not say that such appearances are often found, and there is little doubt that the patient must have had a severe fall during one of the fits. There was, however, in this case, an appearance more rarely met with, there was no falx cerebri; the hemispheres were joined together by cellular membrane, which adhered to either side of the longitudinal fissure. The vessels and sinuses of the dura mater are sometimes gorged with blood. The arteria meningea media is frequently injected to its most minute ramifications. The membrane itself is sometimes also much thicker than natural; small deposits of bone are also occasionally found, particularly on the falx. Dr. M. Hall has directed our attention to the influence of irritation of the membranes of the brain in inducing spasmodic affections (*Med. Chir. Trans.* xxiv. 122). He removed the cranium of a dog; every kind of irritation, puncture, laceration, &c. of the cerebrum and cerebellum was entirely inoperative: when the brain was cut away, leaving the medulla oblongata, to his surprise he found

that laceration or pinching of the dura mater induced peculiar spasmodic movements of the eye-ball, the eye-lids, the head, &c. These effects are probably induced through branches of the trifacial nerve, which, as in the recurrent of Arnold, is well known to impart branches to the dura mater, and which may do so to other membranes within the cranium. This experiment of Dr. M. Hall's is extremely interesting, but I think we should not too hastily conclude from it that irritation of the membranes, as by deposition of bone on the dura mater, or inflammation of the arachnoid, will always produce spasm; for we must remember that the dog's brain was removed, and the spinal marrow, having lost its controlling influence, was in a state most favourable to the production of reflex phenomena.

The glandulæ pacchioni are not more numerous in insanity than in other diseases. I cannot think, with M. Andral and others, that these are the result of disease because they are so universally found; but if they are not they must have some use. Can it be that, imbedded deeply in the inner table as we sometimes find them, they afford additional support to the brain, and prevent more effectually the interference of the hemispheres with each other when we lie on one side? They may be so far the effect of disease (or rather, I should say, of a provision of nature to counteract its effects), if it be necessary that they should be multiplied to ensure a firmer adhesion of the dura mater to the bone, when the weight of one hemisphere, from the presence, for instance, of a tumor, is likely to interfere with the functions of the other. I considered this supposition to be probable from observing in a patient who died of organic disease of the brain a greater number of these so-called glands than I had previously observed.

The arachnoid membrane is very commonly found opaque and thickened: I have seen this in a patient whose insanity was only of five weeks' duration; it depends, however, more upon the intensity than the duration of the disease. The opacity is sometimes general, sometimes partial. It is more frequently met with on the surface of the hemispheres than at the base of the brain: and this accords with the lesions found in acute inflammation of the meninges. M. Foville considers the opacity and thickening of the arachnoid, and its adhesions with the pia mater, not to be the simple effects of inflammation, but of a deposit of albuminous layers.

I have, in some few cases, met with false membranes in the cavity of the arachnoid. Some have believed these membranes to be deposited between the dura mater and the arachnoid. M. Boudet (*Mém. sur l'Hémorrhagie des Meninges*), and others have, I

believe, satisfactorily made out that the false membrane is in the shut sac of the arachnoid. The blood which forms this false membrane is not effused from a ruptured vessel, but exhaled by little and little through the arachnoid; it expands itself gradually in its cavity till it exactly represents a true serous membrane. If its adhering portion be peeled off, the arachnoid will be found beneath; somewhat rough and tarnished, however, from its contact with the pseudo-membrane. After the effusion of blood has taken place the serum is gradually absorbed, and the clot of blood left. If death occurs soon after the effusion, liquid blood is found; if at a more advanced period, a fibrous sheath is seen enveloping the blood; at a still later period, black clots, which become paler and paler till they lose at last their colouring matter (see Boudet).

Mr. A. had an epileptic fit about two months previous to his coming under my care in Sept. 1839, at which time he laboured under dementia. In December of that year he had a second fit, after which there was thickness and hesitation in his speech, with impaired motion of the limbs, particularly of the left leg.

The fits became more and more severe, and terminated in death on May 23d at 10 A.M.

Post-mortem examination, May 25, 3 P.M.

There was much emaciation of the body. The skull-cap being removed presented great inequality in its thickness. The parietal bones were thin and translucent, and had no diploë. The occipital and frontal bones were natural. The dura mater adhered very firmly to the bone, and was much injected with blood. The arachnoid membrane was much thicker and tougher than natural, and here and there over its surface opaque milky spots were observed. In its cellular tissue, on the upper surface of both hemispheres, but more on the right than left side, there was a great quantity of serum effused, which raised it about a line above the pia mater. In the cavity of the arachnoid was a false membrane, exactly resembling it in appearance, between the layers of which was an effusion of dark red blood, spreading on either side in parallel lines from the crista galli to the squamous portion of the temporal bones. The layers were thick and tough, but not so shining as the arachnoid. The upper layer was so closely connected with the arachnoid that at their point of junction the one could not be distinguished from the other. This pseudo-membrane extended from each side of the falx to the temporo-occipital sutures, and from before backwards over the whole of the superior surface of the hemispheres. The parallel lines of dark blood appeared at first like

small arteries, but under the microscope the blood-globules could be distinctly seen, not confined within vessels, but running in the folds of the false membrane. The pia mater separated very readily from the brain. The convolutions were atrophied; externally they were paler than natural; when sliced, there was very little depth of cortical structure. The cut surface of the brain presented numerous bleeding punctæ. The substance was soft and very wet; when taken up in the hand it felt like a spongeful of water. The ventricles of the brain were larger than natural. Five ounces of sero-sanguineous fluid were collected, which had filtered from the brain and ventricle. The cerebellum was natural. On raising the spinous processes of the vertebræ the vessels of the dura mater were enormously turgid. The spinal cord itself was both externally and internally highly injected, and uniformly so from the occiput to the lumbar vertebræ.

In another patient who was admitted into the hospital, November 3d, 1838, and who died of apoplexy, May 18th, 1839, there was not only found a similar membrane to the one above described, but a layer of lymph of a red colour, and resembling a honeycomb, was spread over the whole surface of the pericardium, which was filled with bloody serum.

I have only two other cases of pseudo-membranes in my note-book; they are very similar to the one I have already detailed. The one died of epilepsy, the other of apoplexy.

The arachnoid is sometimes perfectly dry, its surfaces are not lubricated by the smallest quantity of serum. In general, however, there is much effusion of clear transparent fluid into its cellular tissue; it is not often that this fluid is coloured. This appearance must not be taken as an unequivocal proof of inflammation of the arachnoid; for it may be caused by congestion of the veins, or be the result of poverty of blood. Dr. Kellie, of Leith, in his experiments upon animals bled to death, found effusion of serum in the brains of all.

I think that this effusion is often the consequence of atrophy of the convolutions; for I have observed in some cases where the atrophy has been very limited in extent that serum is collected here under the arachnoid, which has shewn no signs of inflammation: upon one or two occasions this effusion of fluid has been so circumscribed by the membrane that I at first mistook it for a transparent cyst.

The most extensive disease of the arachnoid membrane which I have met with in insanity was in the case of a gentleman who died of epilepsy on February 22d, 1838. The duration of his illness was five years and a half. The evidences of his insanity were,

that all his friends were dead, that the whole population of London had been swept off by disease; that our ships were rotten, our banks had stopped, our trade had failed: he latterly sank into a state of complete fatuity.

In the early part of 1839 symptoms of amaurosis shewed themselves; in September he became totally blind. He never had any illusion of hearing, nor was he at any time deaf. There were deposits of the triple phosphates in the urine, but it was not albuminous. He was subject to attacks of vertigo, when he would fancy that he was being run away with in a cart; he would call out to those about him to stop the horse, and would lay hold of a chair to prevent him, as he said, from being jolted out.

Physical symptoms preceding death.—Epileptic fits, followed by fever; twitching of the muscles more on right side than left; no paralysis of arms or legs; difficulty of swallowing two days before death. No reflex action when the finger was drawn across the eyelids.

Post-mortem examination, February 23d, 13½ hours after death.

The body was not emaciated; there was injection of the capillaries in the depending parts; the scalp was natural; the cranium very thick.

The dura mater adhered firmly to the inner table, and was removed with the skull-cap. It was much injected. The veins were loaded with blood.

The arachnoid membrane on the upper surface was universally thickened and opaque, and studded all over with white spots the size of a millet-seed; in the situation of the anterior lobes of the cerebrum it was so thick that I could with difficulty cut it with the scalpel; it was as firm and elastic as fibro-cartilage; at the anterior and centre part of each lobe, there was on this membrane a deposit of bone with sharp spiculæ, the diameter of which was half an inch on the left, an inch on the right side, the spiculæ on the latter being more prominent. The colour of the arachnoid in this part was of a dirty yellow for the space of three inches; it was universally adherent to the pia mater on the anterior lobes; there was much effusion into the subarachnoid cellular tissue, which being collected with the sero-sanguineous fluid from the base of the cranium, amounted to half a pint by measure. The pia mater was much injected. The convolutions externally were pinched and atrophied, the sulci between them were wide, and the vacant space left by the absorption of the cortical structure was filled with the thickened pia mater and serum. The colour of the convolutions was pale externally; their cut surface shewed scarcely any definite line between the cortical and the fibrous struc-

ture. They were paler at their circumference than their base, and in some parts not more than a line in breadth: when a sponge was placed on the surface of the brain it was so soft that a portion of the convolutions came off with it: the white bands which separate the cortical structure into three parts were no where seen. Dark purple points were seen on the cut surface of the fibrous structure, and not the bright red points so commonly found. The substance of the brain was every where softened, and when taken from the skull did not in the least degree preserve its elasticity. The whole of the anterior lobe of the cerebrum of the right side, except the convolutions of the lower surface, was converted into a pulpy mass of ramollissement, the softening being greatest beneath the points of bone of the arachnoid. The lateral ventricles were twice their natural size, and gaped open without elasticity: on the arachnoid membrane lining all the ventricles were deposited innumerable small pellucid shining tubercles, varying in size from a pin's head to a pin's point; these were thickly studded over the optic thalami and corpora striata, and were traced down the iter a tertio ad quartum ventriculum, where they also existed in great number, particularly in the situation of the calamus scriptorius. The anterior cornua of the ventricles were as large as the ventricles themselves. The posterior cornua were also enlarged. The left hippocampus major of the posterior cornua was converted into a cyst containing a limpid fluid with no lining membrane. The optic nerves were one-third their natural size, flattened, yellowish, without any pearly lustre: all the other nerves of the cerebrum were softened. The thalami were extremely soft; the corpora quadragemina were natural; the cerebellum was very soft; the pons varolii and upper part of the spinal cord were much injected. The basilar and internal carotids, to their remotest ramifications, were studded with atheromatous deposits; some of the smaller arteries were quite plugged up by them.

Thorax healthy; heart flabby and contained a firm yellow coagulum; there were atheromatous deposits on the inner lining membrane of the aorta.

Abdomen, stomach, pancreas, spleen, healthy; liver congested. There was a gall-stone in the gall-bladder the size of a marble. The veins of the intestines were congested; their mucous lining membrane was healthy. The kidneys were of a leaden colour and marbled.

The pellucid tubercles of the arachnoid, seen under the microscope, appeared like transparent eggs surrounded by small granules. They were very hard, and with difficulty broken up.

The tubules of the fibrous structure easily

took on the varicose appearance, became granular when the smallest pressure was made, and had no elasticity whatever.

In parts of the anterior lobe (under a one-eighth eye-piece), were seen small round pellucid bodies corresponding exactly with the tubercles on the arachnoid: nearly the whole pulpy mass was composed of these bodies, mixed here and there with debris of arteries, and granular structure without any trace of fibrous structure. These small tubercles were composed of many other tubercles, and appeared like a bunch of grapes.

Adhesions of the pia mater are found with the arachnoid on the one side, and with the convolutions on the other. It is sometimes much thickened, and in recent cases generally injected. If we wanted other proofs of the variation of the quantity of blood, and of the state of the capillary vessels, in insanity, we should find them here. I have seen the colour of the plexus choroides in some cases a bright red, in others of a dirty white, or quite blanched. Sometimes arterial, sometimes venous congestion is found: I have seen this plexus loaded with varicose veins.

I have now to mention the alterations in the cortical structure. In acute mania the convolutions have a tendency to hypertrophy, in chronic mania to atrophy. In acute cases their external surface is round, and their colour intensely red. In chronic cases it is flattened and pale. As there is so much difference between the appearance of the one and the other, it will be more convenient if I first describe the morbid alterations found in the acute stage of the disease, and afterwards those found in the chronic.

In acute cases the pia mater is seldom found adhering to the surface of the hemispheres; the convolutions are well developed; when cut there is as well defined a separation between the cineritious and fibrous structure as in a healthy brain; the white bands may be traced in every part running parallel to the external and internal surface; but the cortical structure is much injected, and what is called the marbled appearance by French writers is very generally seen. Foville has frequently observed small red points in the marbled lines, which appear to him very small effusions of blood, afterwards converted, he thinks, into cysts filled with serosity.

The chronic alterations of the cortical structure are more marked than those of the acute. The pia mater frequently adheres to its surface; and a layer of softened grey matter is sometimes separated in the attempt to peel it off. The diminution of bulk takes place both on the surface and in the centre of the convolutions; so that wide sulci are left between the folds, and a very thin layer is spread over the fibrous structure; the

white bands have either disappeared, or the colour of the ganglion globules is so faded that they cannot be distinguished. The external layer of the cortical structure is sometimes firm, while the internal layer is soft. It then assumes the appearance seen in Dr. Bright's Work, Plate 1, fig. 6. Medical Reports, Vol. ii.

Softening of the substance of the convolutions is either partial or general; it is sometimes confined to one or two folds; sometimes to one, at other times to both hemispheres.

The two following cases of acute and chronic insanity may serve to exemplify what I have said of the difference of appearance of the brains of each after death.

A woman, æt. 39, who had suffered under mania with violent paroxysms of furor, was brought to the hospital, October 28th, 1842, in a dying state. She died October 29th, at 6½ A.M. of exhaustion. The duration of the insanity was 10 days. Her occupation was a dress-maker. The cause of her illness was disappointment in her affections.

Post-mortem examination, October 29th, 13 hours after death.

The body was bloodless and emaciated. The skull-cap thin: in the centre on the right side was an indentation which nearly pierced through the parietal bone; it corresponded with a swelling the size of a small marble, where the arachnoid had collected some effused serum. The vessels of the dura mater were turgid; the arachnoid membrane was every where transparent; fluid was effused into its cellular tissue. The pia mater separated with some difficulty from the convolutions, but did not tear them: its veins were much injected. The cortical structure was both externally and internally of its natural colour and consistence; the white median bands were well seen. The convolutions were sharply cut, and in high relief. The arteries were distended with blood. The cut substance of the brain presented a deep blush of red throughout the cerebrum, cerebellum, pons and medulla oblongata, but more especially in the region of the posterior lobes, where there was also more serum effused. The lateral ventricles were rather large, and contained more fluid than natural. The substance of the brain was firm. An ounce and a half of sero-sanguineous fluid was left in the base of the cranium.

Thorax.—Some firm adhesions of the pleuræ on the left side; lungs, heart, liver, gall-bladder, spleen, pancreas, and stomach, healthy. Left kidney healthy; right slightly marbled; both of the natural size. Mucous membrane of the ileum very slightly injected. No ulceration present.

A woman, æt. 51, who had been a boarder or uncured patient in St. Luke's, since

January 1833, died January 7th, 1843, of phthisis.

The duration of her insanity had been 16 years.

Evidences of her madness.—Incoherent; imbecile.

Physical symptoms prior to death.—Dulness of percussion over the whole of the right side of the thorax; no respiratory murmur heard here. There was scarcely any expectoration. Anasarca of the left leg.

Post-mortem examination, January 7th, 8 P.M.

The frontal bone receded very slightly from before backwards. The body emaciated and bloodless. After the skull-cap had been removed, the diploe were found to have disappeared, except in a small portion of the frontal and occipital bones. There was a small depression in the centre of the inner table of the occipital bone, which was translucent; there was another in the frontal bone.

The *dura mater*, externally, was much injected with red blood. The *arteria meningeæ media* was large; the membrane adhered firmly to the bone. The arachnoid was dotted all over with minute opaque spots; into its cellular tissue yellowish transparent serum was effused throughout its whole extent.

The *pia mater* was rather more injected than usual; it separated from the convolutions without tearing them. Under the hollow of the occipital bone, above described, the convolutions were flattened and atrophied for three lines in extent on either side of the longitudinal sinus; the arachnoid had here formed a circumscribed cyst. The cortical structure externally was pale. Its outer layer was soft, and separated readily from the external white band, under which the substance was firm and of a reddish hue in the frontal region. Serum was infiltrated into the substance of the brain, and about three ounces of fluid were left in the basis of the brain. There were numerous bleeding punctæ on the cut surface of the cerebrum and cerebellum; the pons and medulla were also injected. Their substance was firm. The ventricles were rather larger than natural; the hippocampi not altered. The basilar artery was joined by two internal carotids; one pair of which was much constricted and of the size of a pin, and small atheromatous deposits were upon it. There were small dots of extravasated blood of a dark red colour, the size of a pin's point, in the right lobe of the cerebellum.

Thorax.—Slight adhesions of the pleuræ on the left side—the lung healthy; universal adhesions of the pleuræ on the right side—the lung was with difficulty taken out; it was studded all over with miliary tubercles; there was

a dark vomica near its apex and posterior part. Heart healthy, small, a firm dark coagulum in the left ventricle; stomach, spleen, pancreas, healthy; liver pale, of a dirty white colour, and of a fatty consistence; kidneys small, and very slightly marbled; their capsules were with difficulty separated. Intestines—there was a small portion of the ilium constricted to the size of the little finger, extending about a foot; the mucous lining membrane was here injected.

Alterations of the fibrous structure.—Upon slicing the substance of the brain numerous bleeding punctæ from the gaping mouths of the vessels are frequently seen, giving it the appearance of being sprinkled with sand—the *aspect sablé* of French writers. This varies in intensity from the few specks seen in healthy brains to patches of extravasated blood, a deep blush, or marbling and mottling over the whole surface [Bright's plate]. We have a salutary warning from Dr. Seymour not to lay too much stress upon this appearance. "There is, perhaps," he says, "no appearance to which more importance has been attached than to congestion of the vessels of the head; the mechanical physician having his scruples satisfied by a very slight injection of the vessels of the brain, while the morbid anatomist must have observed almost every variety of intensity of this appearance often unattended by corresponding symptoms of excitement, or disturbance of the brain, during life." As a proof that these remarks of Dr. Seymour's are just, I may state that I have met with some brains in madmen marked by the entire absence of bleeding points.

In speaking of the hardness or softness of the brain of lunatics I shall not refer to cases of a questionable nature, as every one must have seen much variety of density in this organ, depending upon the time of making the examination after death, and the season of the year. There are some brains of lunatics which are remarkably tough and elastic; when they are taken from the cranium they preserve their shape perfectly, and when you attempt to cut them you will think your scalpel is blunt, however sharp it may really be: these brains appear like hard albumen. On the other hand, the brain of the lunatic is found remarkably soft; and when taken in the hand feels like a wet sponge. Ramollissement is not very uncommonly met with. I have found the greatest degree of softening correspond with a spicula of bone either adhering to the cranium, dura mater, or arachnoid. I have, however, likewise found it accompanied with atheromatous deposits on the arteries; and, on the other hand, I have found a spicula of bone pressing on the convolutions without any sensible alterations in the part pressed upon.

Tubercles are not often met with in the substance of the brain; their slow growth rarely interferes with the functions of motion or sensation; if, towards the close of the disease, there is aberration of intellect, it partakes more of the nature of delirium than insanity.

The ventricles are frequently distended with fluid; their walls are also found gaping and inelastic. I have sometimes seen vesicles on the choroid plexus, and once I found sabulous matter deposited in it when it was absent in the pineal gland. This gland I have seen converted into a transparent cyst, a morbid appearance which would have been highly prized by a disciple of Descartes.

The pons varolii is occasionally found injected. Upon one occasion I found one half highly vascular, the other half natural; upon another occasion I found a lesion in an interesting case, which I will detail to you. A young woman was admitted into the hospital March 19th, 1841. She was a nurse, and was seized with mania on March 14th. The cause of her illness was stated to be anxiety in having to leave the children of whom she had the care, as she was about to be married. The evidences of her insanity were incoherence, excitement; she fancied she was nursing a child, would sing, and rock herself backwards and forwards, &c.

Physical symptoms.—Very weak and emaciated; when she attempted to walk she staggered from side to side as if she was drunk. March 27th she was attacked with fever; violent convulsions soon after showed themselves, which succeeded one another very rapidly. She died April 2d, 1841.

Post-mortem examination, April 2, half-past 9 P.M.

Body emaciated. Dura mater more injected than natural. Arachnoid and pia mater healthy, except that the vessels of the latter were turgid. Convolutions and cortical structure natural. Substance of the brain firm. On slicing it to the centrum ovale, a remarkable difference between the anterior and posterior half presented itself, the former being of a natural colour, the latter of a deep red; the division between the white and red colour was so defined that a line drawn from ear to ear separated the one from the other. Fluid blood was effused over the surface also of both posterior lobes; there was more than an ounce of blood left in the basis cranii. On cutting into the pons varolii an apoplectic cyst was seen, the blood contained in it being changed and mixed with the broken-down substance of the pons. *Thorax.*—The lungs did not collapse on opening the chest; they felt solid, but a piece placed in water floated. The bronchi were gorged with frothy mucus, and were deeply injected. Heart.—The

auriculo-ventricular ostium on the left side was so small that it hardly admitted the point of the little finger to pass through, as the mitral valve was nearly obliterated, not by disease, for it was perfectly smooth, but by a malformation. The parietes of the left ventricle were thinner than natural; those of the auricle thickened and dilated. The uterus of a dusky brown colour, from engorgements of the vessels. Spleen, liver, kidneys, ovaries, intestines, healthy.

It now only remains for us to consider the morbid appearances of the nerves. The evidence upon this part of our subject is not so satisfactory as one could wish; we cannot, however, be surprised at this, considering how difficult it is to detect disease of the nerves even in those cases where there has been great functional disturbance existing in them during life. Disease may spread along a sensitive nerve, gradually affecting it till the spinal marrow becomes involved; and it is probable that the same may take place with regard to the brain.

In January 1839, I attended a gentleman who laboured under general paralysis occasioned by taking large quantities of morphia to relieve the pain of *tic douloureux*, for which the supra-orbital nerve of the right side had been divided previously. He died on the 22d Feb. 1840. At the post-mortem examination I found three sharp spiculæ of bone on the ridge of the petrous portion of the temporal bone under the fifth and seventh nerves. In tracing the auditory nerve to its origin in the fourth ventricle, the *iter a tertio ad quartum ventriculum* was found inflamed, and the floor of the fourth ventricle presented a deep blush of red, and was somewhat softened, the transverse white bands being involved. In this case hearing was perfect. "In the museum at Berlin," according to Müller, "there is the brain of a young female who, in consequence of a fall upon the neck and occiput, was gradually attacked by paralysis of the whole body; and here, upon the floor of the fourth ventricle, and upon these transverse white fibres, an effusion of lymph had taken place, although the sense of hearing had not suffered. We must, then, agree with him that these bands have by no means the important influence on the sense of hearing which is often attributed to them."—Baly's Trans. 828.

Disease at the origin of the nerves, although the most careful anatomist may fail to detect it, is doubtless frequently the source to which the subsequent delusion may be traced.

A patient under the care of my father in 1813, imagined that snakes were crawling about his arms, and frequently asked for a knife to cut them out. At the post-mortem examination, on opening the spinal canal, something having the appearance which

effused blood assumes after it has been deposited a considerable time, was discovered lying between the processes of the vertebrae and the membrane; this substance was nearly two inches and a half in length, half an inch in breadth, and one-sixth of an inch in thickness; it extended from the 3d to the 5th cervical vertebra, and adhered firmly to the bone.

In a patient who died of epilepsy combined with general paralysis, and who fancied that wild beasts were tearing the flesh off his back, I found the membranes of the spinal marrow injected, and the minute vessels of the cord much inflamed in the cervical region: its cut surface, from the situation of the 1st to that of the 7th vertebra, presented a deep blush of red.

It will be needless that I should take up your time in detailing minutely the morbid appearances which I have found in the viscera of the thorax and the abdomen. I shall merely state them in a general manner.

In 50 cases, which I select from my case-book, where the thorax and abdomen were examined the lungs, were diseased in 31.

Adhesion of the pleuræ . . .	in 25
Effusion into . . .	11
Pneumonia.	13
Bronchitis	5
Tubercles and Vomicæ	8
Emphysema	3
Gangrene	2
The heart was diseased in . . .	25
Hypertrophy	12
Diseased valves	10
Hypertrophy with dilatation . .	2
Atrophy with dilatation	3
Fluid in pericardium	4
Flabby	6
Alterations in the liver were observed in	12
Congested in	3
Gall-bladder contracted without bile	2
Gall-stones.	5
False membrane on surface . . .	1
Fatty degeneration	1
Granular	1
Disease of the kidneys	19
Disease of the uterus and ovaries .	7

I must say, in justice to M. Pinel's theory, that in the majority of the cases the intestines were only partially examined, as I often had to work single-handed, and had not completed my labours when the friends came for the corpse.

The intestines were found diseased in	12
Mucous lining membrane injected in .	6
Ulceration in	1
Stricture in	3
Arch of the colon displaced in . . .	2

In concluding the observations I have to

make on the examination of the brain of insanity, I have to draw your attention—1st, To the many different morbid appearances which accompany the disease; 2dly, To the many similar appearances which give rise to its different species, and are found where insanity does not exist; the best proof of which is, that I have been able to illustrate many of the post-mortem alterations by the plates of Dr. Bright and Dr. Carswell.

Now although we may look to the cortical substance as giving us the most conclusive evidence of variations from healthy structure, yet we are far from being able to say in what the first departure from such healthy structure consists. Do we call it congestion? This is the mere effect of something which has caused previous irritation: we know well how different in their nature the causes are which produce congestion—whether passion, over-exertion of intellect, diseases of the heart and lungs, stomach and intestines, narcotic poisons, &c. It would appear, then, that beyond what morbid anatomy teaches us, there is some change in the brain which, influenced by individual susceptibility, is the primary cause of the various phenomena which we recognise in madness. In this, as in every other disease, morbid anatomy alone cannot guide us in establishing just views of pathology. It is the better, perhaps, that such is the case, as it makes us attend more particularly to the symptoms during life, the relief of which is of far greater importance than a correct knowledge of the primary source of the disease.

OBSERVATIONS

ON

CERTAIN SOURCES OF FALLACY IN THERAPEUTICS:

THEIR CAUSES, CONSEQUENCES, AND THE
MEANS OF PREVENTING THEM.

BY ROBERT VENABLES, M.B. &c. &c.

(For the London Medical Gazette.)

THERE are fallacies in anatomy; fallacies in physiology and pathology; and, what is of still greater moment, fallacies in medicine. Hence it is that virtues are frequently ascribed to particular remedies, which subsequent experience or more ample and careful observations refuse to confirm. This is much to be lamented; because, from a first disappointment, really valuable remedies are often consigned to *unmerited neglect*. In illustration it will *only perhaps be necessary to state the*

following facts, and to show that careful and cautious examination into all the circumstances is essential to guard against over hasty and unfounded conclusions.

A bottle of urine, containing about half a pint, was presented to me, with a request to examine it, and report the result. I was informed "that, on examination previously, it was found highly *alkaline*, and strongly effervesced on the addition of an acid." The urine when presented to me had been standing at rest for some days, was clear and transparent, of the natural colour, devoid of smell, unctuous to the touch, deepened the natural blue of litmus paper, but strongly affected turmeric, turning it to a reddish brown. To the bottom of the vessel had subsided a layer of a whitish-looking powder, somewhat coloured apparently by the colouring matter of the urine. This powder, on subsequent examination, proved to be the triple phosphate, with a small proportion of the earthy carbonates*. Thus, it dissolved with slight effervescence in diluted hydrochloric acid, and fused into a globule before the blowpipe. The specific gravity of the urine was found to be between 1.033 and 1.034. Such were the more immediate phenomena in this case.

This being considered a case of highly alkaline urine, and presenting a fair opportunity of testing the efficacy of benzoic acid in restoring alkaline urine to its natural acidulous condition, as urged by Mr. Ure†, ten grains of this acid were given as a dose, and repeated three times, the patient taking thirty grains in all between this and the subsequent visit. The urine examined on this occasion was found to possess its natural acidulous reaction upon litmus paper, did not effervesce with the strong acids, threw down no sediment, and presented the ordinary sensible properties.

The inferences about to be drawn from the phenomena and facts above stated were—

1. That the urine, when passed from the bladder, was in a highly *alkaline* condition.

2. That three doses, or thirty grains, of benzoic acid—in conformity with the views of Mr. Ure, that this acid

* I have since ascertained that such would be the result of those re-actions, which must have occurred in the present instance.

† See M&D. GAZ. Feb. 10th.

undergoes decomposition *in transitu*, and appears in the urine as *hippuric acid*—had sufficed to restore to this strongly alkaline urine its normal acidulous reaction. Several of the phenomena, however, above described, appeared to me wholly irreconcilable with any of the observed and known morbid states of urine, and even in themselves quite incompatible. The urine is very seldom alkaline when first voided. Even in the phosphatic diathesis it is either neutral for the most part, or even acidulous*, becoming alkaline—in a time greater or less, in proportion to the severity of the diathesis—after being passed †. The only marked exception is when the mucous lining of the bladder, in a diseased state, throws off a large quantity of vitiated mucus, the fixed alkali of which reacting on the urea converts this principle into carbonate of ammonia in the bladder, and the urine then has an alkaline reaction even when first passed. In such cases, too, the urine, if not actually putrescent when voided, speedily putrefies, and exhales a strong ammoniacal odour. Such were the facts in the case detailed by Mr. Ure.

But the case under consideration presented no such phenomena, and, although strongly alkaline, yet, after having stood for four or five days, presented no turbidness, no alkaline odour, nor any mucous subsidence. The specific gravity, too, 1.033, greatly exceeded any compatible with the sensible conditions or properties presented, and could only, pathologically considered, result from either the presence of sugar, or an excess of urea. The presence of sugar was negatived by the sensible properties—the large deposition of the triple phosphate, the strongly alkaline state, and the capability of effervescence. Neither the nitric nor the oxalic acid, after four hours, separated any urea, and consequently this principle ‡ could not have been the cause of the high specific gravity. The usual reagents, also, shewed that the urine was completely freed from its earthy principles, as neither caustic potass, nor even oxalate

of ammonia, precipitated a single particle of earthy matter.

The anomalous characters and irreconcilable phenomena presented by the urine in this case inclined me to suspect one or other of the fixed alkalies in a carbonated state as their source, and I determined, in the first instance, to examine for potass, as admitting of more positive identification. For this purpose, a portion of the urine was diluted with rather more than an equal volume of water in a test-tube, and to it a concentrated solution of tartaric acid was added in considerable excess; violent effervescence took place, and a large quantity of the crystals of bitartrate of potass speedily subsided, and which, when completely deposited, exceeded in bulk the volume of urine employed by about one-half. A volume of the urine undiluted, treated in the same manner, instantly became a solid mass of crystals of cream of tartar. On adding to a portion of the same urine a solution of chloride of calcium, a large quantity of chalk, or carbonate of lime, separated and speedily subsided. Thus the presence of potass, and of carbonic acid, in large proportion, were unequivocally proved.

The facts above stated leave no doubt but that the anomalies furnished by this case arose entirely from the artificial impregnation of the urine with carbonate of potass, and that this impregnation had been effected after the urine had been voided from the bladder. The presence of carbonate of potass does not form the principal feature in the anomaly, as it is well known that the citrate, tartrate, acetate, &c., are converted *in transitu*, and appear as carbonate of potass in the urine, and may be detected and identified by the appropriate methods. But no bladder, however hardy or callous, could tolerate, even for the shortest period, urine so highly loaded with carbonate of potass; nor could it endure even the injection of water so strongly alkaline. The urine in this case was capable of dissolving, or at least of disorganising, the cuticle, as was manifested by the unctuousity of feel which it communicated. I found that it takes nearly half an ounce of carbonate of potass to raise the ordinary specific gravity of half a pint of urine to that of the specimen in question.

A question here naturally presents; how was the impurity in this instance

* The term acidulous is to be understood as referring to the reaction on litmus paper.

† See Guide to the Urinary Cabinet, &c.

‡ Subsequent observation shewed this principle to be, if not actually deficient, at least in no excess.

effected? was the adulteration intentional, with a view to imposition; or was it the result of accident rather than design? Although I think we may generally attribute such contaminations to design, yet I have been informed that in this instance there was no assignable motive; on the contrary, that many circumstances concur to lead to a diametrically opposite conclusion. But although these circumstances may acquit the individual of any attempt at intentional deception, still they will not alter the absolute facts. The alkaline impregnation might have been the result of accident, from not carefully examining the vessel into which the urine had been just passed, or into which it was subsequently transferred*. Be this as it may, still the history presents matter by no means uninteresting in several points of view: first, it shews how careful and diligent we should be in the examination and analysis of morbid phenomena, especially if intended as the basis of either pathological or therapeutical inductions. It proves the necessity of great caution and circumspection before we admit the natural existence of such phenomena, more especially if of an anomalous or incompatible nature; and that we do not reason upon nor draw conclusions from equivocal facts. Secondly, how much more rigidly and strictly we should analyse the various phenomena, and examine their compatibility, when we intend them as the foundations for special therapeutical axioms.

To apply these principles in the present instance, it is evident that a blind confidence in the obvious phenomena, and an over anxiety too hastily to corroborate new theories or modern discoveries, might have led to serious errors, not only as regards pathology, but also therapeutics. The three doses or thirty grains of benzoic acid might have been supposed capable of rendering even the most strongly alkaline urine acidulous, as the urine passed on the first visit after taking benzoic acid, but in the presence of the practitioner, was found, so far from possessing any alkaline property, to be naturally and unequivocally acidulous. A therapeutical fact, especially if new and previously unobserved, commands attention, and interests in a degree proportionate to

its value in pathology, or the benefits which it is likely to confer upon practical medicine; hence it must be evident that a rigid examination of the premises is as essential to correctness as that of the conclusion. The conclusion may be legitimate, but still, if the premises be unfounded or erroneous, evidently the conclusion must be false.

There is no department of medicine more subject to fallacies of this sort than that of urinary diseases. This, perhaps, is owing to various causes: first, to the little attention given by earlier observers to the subject in question; secondly, the ease with which superficial observers may be imposed upon, either through accident or design. But it is to be hoped that the greater assiduity, and the greater degree of importance attached to this particular subject by more modern inquirers, will greatly limit both such fallacies and their ordinary causes.

Since the above, two cases of alkaline urine have presented to me, in which the urine was alkaline, or at least neutral, even when passed from the bladder; and the general details, perhaps, may form a useful contrast to the above. They both occurred within a few days of each other.

April 29th, I visited Mr. G—, who came to London from the country in consequence of the state of his health. He complained of pain in his loins, and pain in the urethra, especially near the orifice, on passing water. Had frequent desire to pass water, and was obliged to get up frequently in the course of the night to pass it. The urine on being voided was muddy, alkaline, or perhaps rather neutral, not rendering turmeric brown, although litmus reddened by a very weak acid was after a minute or two turned blue again; the specific gravity, 1.022, never getting lower than 1.020 during the four weeks that I have been attending, at least twice in every week. Heated, the urine coagulated; and this took place by nitric acid. On being allowed to remain at rest it did not become clear, but deposited a quantity of purulent-looking matter, intermixed with blood, the red particles distinctly shewing themselves. There was no excess of urea; on the contrary, this principle might be considered, if anything, deficient. A strong acid caused slight effervescence, but

* This specimen was brought to, not passed in the presence of, the medical practitioner.

nothing like what occurred in the former case. It seemed to depend upon the presence of carbonate of ammonia. The earthy bases were not in excess.
